Preface

The main objective of the following ERTS-1 work was to exploit satellite-obtained multispectral data for Great Lakes observations. Near-coincident NOAA-2 satellite data have also been utilized to provide additional information in the thermal-infrared part of the spectrum.

A broad-based approach enabled us to develop techniques for monitoring high concentrations of surface biomass and algal blooms in the Great Lakes during late summer and early fall. Chemical precipitation in the near-surface layer is readily observed by ERTS-1 and was found more extensive than previously believed. These "whitings" have been seen observed as regular summer and fall events in three of the Great Lakes--Lakes Michigan, Erie, and Ontario.

The high resolution of the MSS instrument permitted ice vector movement studies on successive days where overlapping data were available. These opportunities were infrequent in the Great Lakes because of the extensive cloud-cover that normally occurs in the study area during the winter months.

Water color displays a positive correlation with surface water temperature during the spring and early summer months as the surface water becomes increasingly warmer. This correlation reverses for fall and early winter. Since most of the color in the Great Lakes is due to river effluents or shoreline erosion (the lakes were at record high levels during all of our observations), the resulting turbidity is found principally in the nearshore regions. The correlation was anticipated as it is these shallow nearshore waters that respond most quickly to warming in the spring and cooling in the fall.

Of all our ERTS-1 findings the most troubling was the extensive

sun glint contamination. At the latitude of the Great Lakes the effect of glitter was most obvious from April to August. Although contamination of the imagery (water scenes only) is possible for solar elevations below 50° it is most apparent when the sun elevation exceeds 55°. A model is employed to permit a better understanding of these effects. Glint becomes most troublesome at the low wind speeds typical of clear sky conditions, i.e. those needed for ERTS-1 observations.

The final, and most rigorous, study presents a nearly-complete set of circulation charts for five Great Lake areas that revealed numerous natural color tracers: southern Lake Michigan, southern Lake Huron, Lake St. Clair, Lake Erie and Lake Ontario. These charts were further categorized by a weighted three-day resultant wind stress. Whenever possible these derived currents were compared with previous analyses of lake currents.

Our Great Lakes ERTS-1 study resulted in the following recommendations for future investigations:

The ERTS System

- (1) Incorporate a thermal-infrared detector as an additional MSS channel.
- (2) Consider a sensor-pointing capability to avoid the sun glint problem under high solar elevation,
- (3) Add multispectral capability in the blue region (0.45-0.5 μ m) of the spectrum for better "whiting" and biomass detection.
- (4) Provide quantitative radiances.
- (5) Develop better calibration techniques to prevent banding in future sensors.

- (6) Provide additional amplification for the low radiances typical of water scenes.
- (7) Consider an orbit closer to local noon. Geometry permits high solar elevations for better water color data and increased depth penetration capability. A pointable sensor is essential for a noon orbit to avoid sunglint effects along the sub-satellite track.
- (8) More frequent coverage is essential for coastal work.

Algal Studies

- (1) Further investigate a correlation of surface chlorophyll and biomass with low level variability in 0.7-0.8 μ m data.
- (2) Investigate other lakes and periods for high surface concentrations of algae using the classification developed in the study.
- (3) Compare Great Lakes classification signatures with oceanic observations (red tides, etc.).

Chemical Precipitation

- (1) Develop a classification technique for monitoring the depth of the upper level of whittings.
- (2) Investigate relationship of radiation intensity observed in 0.5-0.6 μ m data to the concentration of calcium carbonate.
- (3) Monitor changes in evolution of whiting events.
- (4) Survey other ERTS-1 data for similar classifications in oceanic areas. Whittings reportedly occur in such regions as the Florida Keys and Persian Gulf.

Ice

- (1) More frequent coverage is needed to monitor ice movement in the Great Lakes, although in overlapping areas ice motions may be charted over two-day intervals.

- (2) Ice condition information is augmented by the multispectral approach (especially the 0.8-1.1 μ m channel), but could benefit from additional spectral data in the near-infrared (wavelengths up to 2 μ m).

Sunglint

- (1) Calm water areas could be charted readily using images contaminated by sunglint; information on glitter probabilities should be provided all marine and lake investigators.
- (2) Oil spills and other pollutants with similar capillary wave damping attributes are easily detected in sunglint highlight areas; more work seems appropriate in this area for automatic classification.
- (3) Current boundaries frequently provide contrasting roughness fields that are enhanced by sunglint.
- (4) If more quantitative radiance data could be gleaned in sunglint regions, the surface wind field could be calculated.

Circulation Mapping

- (1) Some resultant wind stress conditions were not observed in all of the five areas studied. These omitted wind directions should be incorporated as they are observed during subsequent cloud-free overpasses.
- (2) Additional areas in the Great Lakes should be monitored for circulation features as conditions permit. Lake Superior was not included in this study; portions of that lake have the extensive turbidity needed for circulation observations.
- (3) Refinements of the circulation charts become more tentative in those areas most distant from the wind stations used.

Appendix	A-1

The guarded optimism expressed by the oceanographic community prior to the launch of ERTS-A gave way to surprise and elation as the first ERTS-1 images became available during August 1972. The multispectral scanner subsystem (MSS) imagery provided the following during the first few weeks of observations: (1) an image of the Monterey area that pinpointed location and extent of the near-shore kelp beds; (2) an image of Rhode Island Sound that displayed numerous turbidity tracers for surface circulation; and (3) a Great Lakes image that produced the first indication that western Lake Superior was indeed colored red by suspended clay particles (Strong, 1972).

Our original test area was composed of Lakes Erie and Ontario. However, as we quickly became enthusiasts of the ERTS-1 MSS data we felt we were doing the Great Lakes a disservice by not including Lakes Michigan and Huron as well. Lake St. Clair was included for completeness. A chart in Figure 1 provides an overview of the area covered in our ERTS studies. (Chesapeake Bay initially had been included in our proposal to NASA/GSFC, but this study was omitted after finding many other investigators were covering this estuary. We were to have studied ice in Chesapeake Bay; however, due to very mild winters ice was rarely observed in the open bay.)

The ERTS-1 MSS data have been used primarily in their raw (basic) image form for this study. Computer compatible tapes (CCT) have been employed in selected instances to produce printouts, or they were processed for computer enhancement using a NOAA/NESS Digital Muirhead Device (DMD). General Electric's "Image 100" and the Environmental Research Institute of Michigan's (ERIM) multispectral processing equipment were used in some portions of our study.

Figure 1. ERTS-1 Great Lakes Coverage Chart. Stippled area indicates image overlap along individual orbits.

The bulk of our work has been directed toward the production of circulation atlases for the following lakes:

- (1) Southern Lake Michigan
- (2) Southern Lake Huron
- (3) Lake St. Clair
- (4) Lake Erie
- (5) Lake Ontario

Results for these five areas were presented in Chapter 7 and take advantage of river discharges and lake turbidity that are natural current tracers. Using all observations with cloud-free data between August 1972 and December 1973 enough observations were available to classify circulation as a function of wind stress.

Five chapters are included that discuss special observations made under this NOAA/NASA effort:

Algal Blooms - Chapter 2

Chemical Precipitation - Chapter 3

Ice - Chapter 4

Sunglint - Chapter 5

Surface Temperature vs. Color - Chapter 6

Portions of this chapter were first presented at the NASA Symposium on Significant Results obtained from the ERTS-1 (1973) and later amplified in Remote Sensing of Environment (Strong, 1974). An understanding of what was observed in Lake Erie was provided by an excellent image of a documented algal bloom in Utah Lake observed by ERTS-1 on 12 September 1972.

Introduction

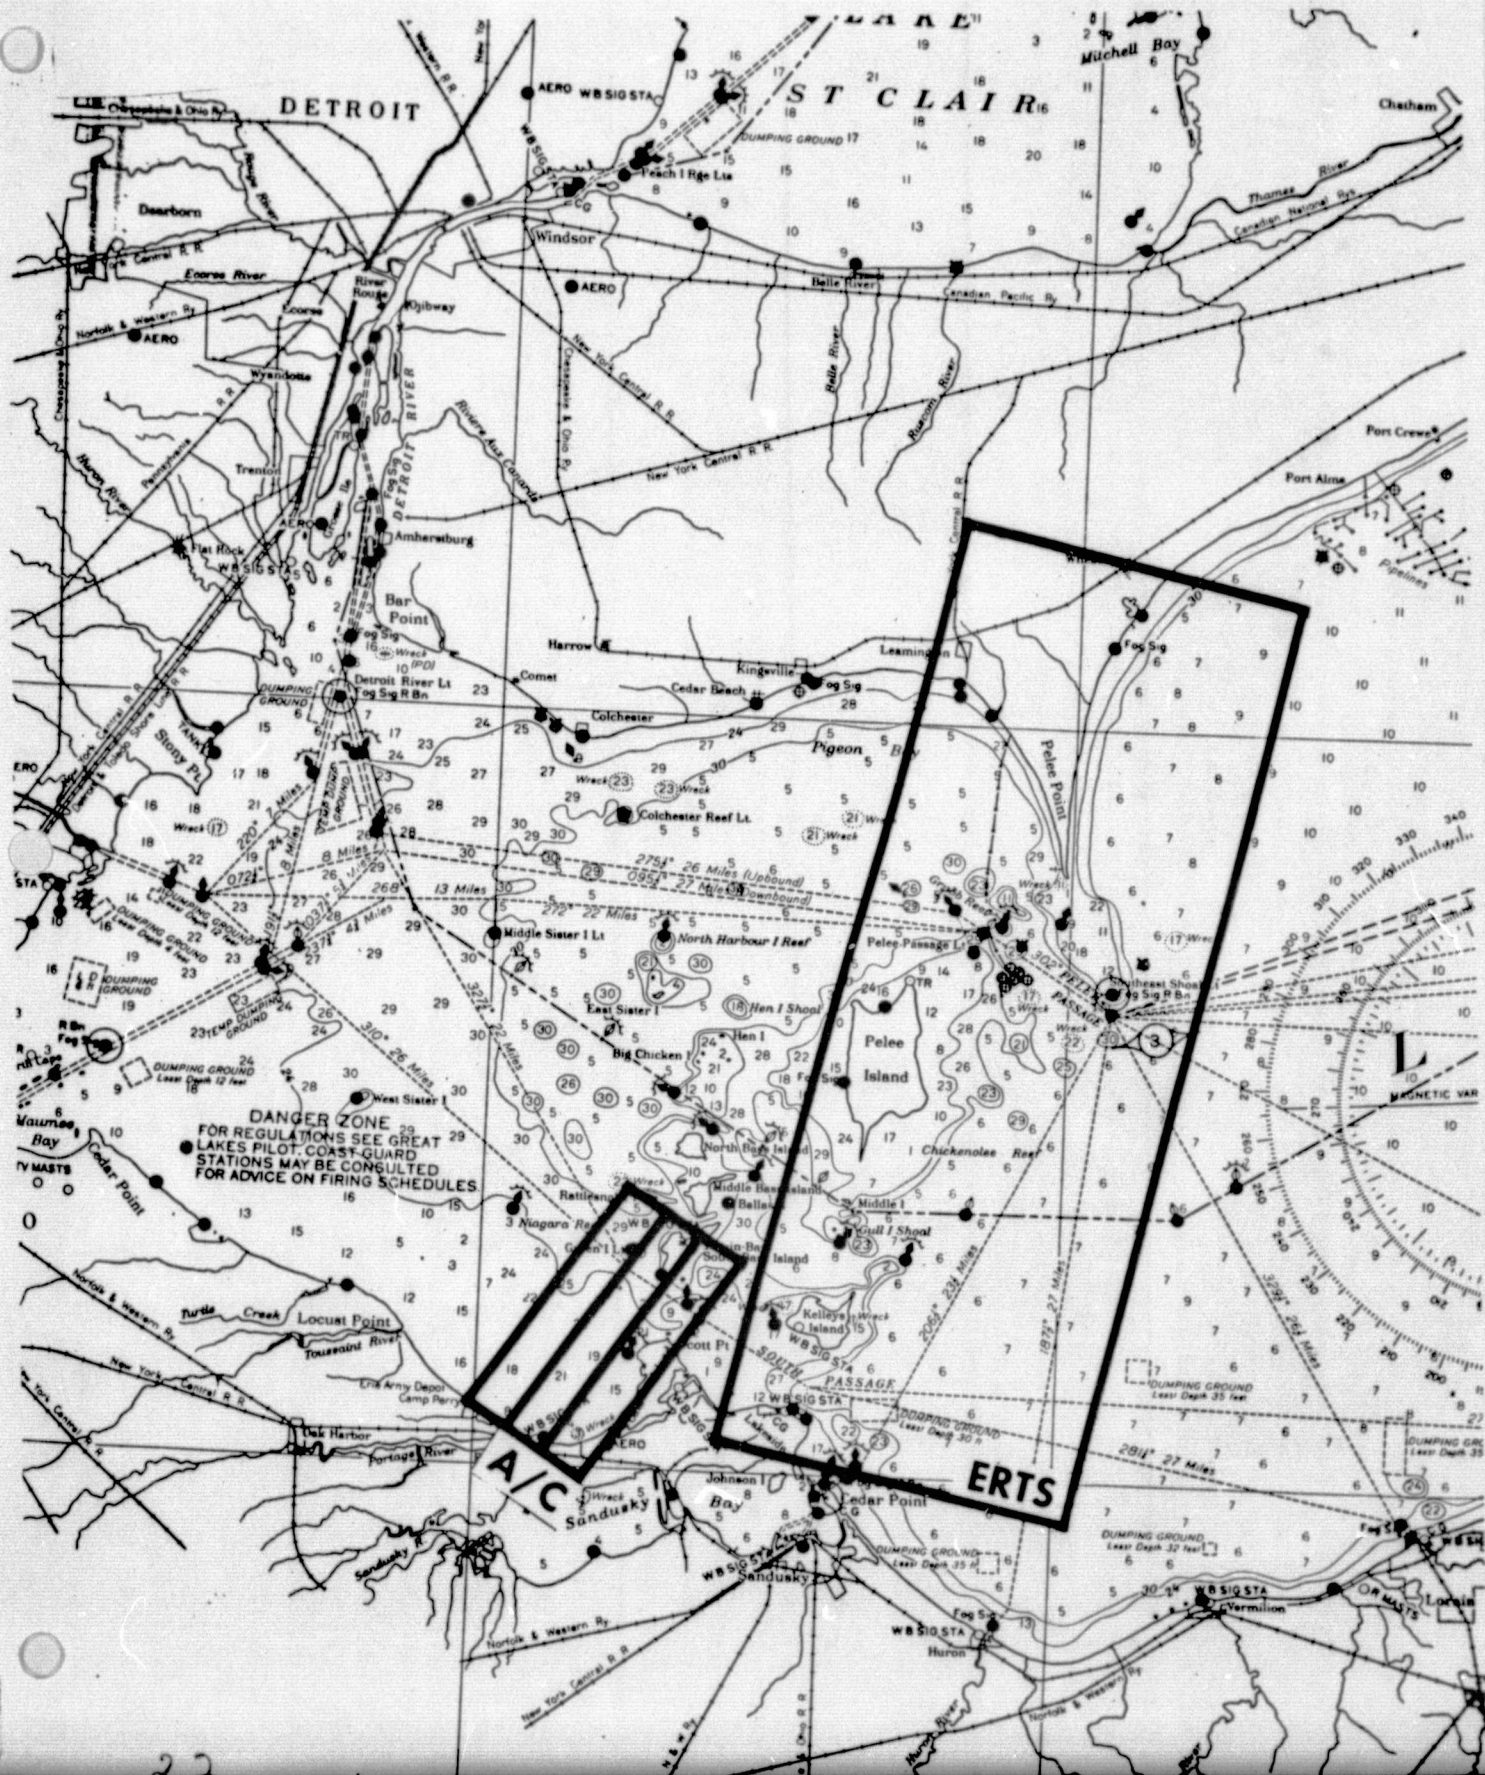

As NOAA aircraft flights were being made over Lake Erie on 15 October 1972, underflying the ERTS-1, a long dark streamer was observed between Kelleys and South Bass islands and the Ohio shoreline. Although it was known that the ERTS-1 multispectral scanner subsystem (MSS) image swath would cover a 100-nautical-mile-wide strip just east of this area (NASA, 1971), the aircraft flight pattern was modified extemporaneously to provide sufficient coverage of this waterborne material. A chart in Figure 2 shows the location of the aircraft and satellite imagery used in this study.

Observations and Results

The NOAA Buffalo DeHavilland aircraft was equipped with a Spectral Data Corporation four-band camera system for spectrally simulating the ERTS MSS. Overlapping photography, through the boresighted camera, viewed a swath 4.6 km wide beneath the aircraft from an altitude of 5.8 km. The purpose of the high resolution photography was to avoid any interpretation difficulties that might arise during examination of the 100-m resolution ERTS-1 imagery.

A Daedalus Dual-Channel Thermal Scanner was also incorporated into the aircraft flight package. The two thermal-infrared channels covered the 3.5-5.0 μ m and 8-13 μ m atmospheric "windows". This imagery was centered directly beneath the aircraft and provided an 11-km wide swath from the 5.8-km altitude. The thermal-infrared imagery provided further lake

Figure 2. Chart of Western Lake Erie. The area covered by aircraft thermal scanner is the rectangle marked A/C; the interior elongated box shows the area covered by photography. To the right, the area covered by the ERTS-1 enhancement shown in Fig. 5 is the rectangle marked ERTS.

surface information that was related to the color patterns observed by both the aircraft and satellite sensors.

Since our main surface-truth operations were being conducted along the Canadian shore of Lake Erie, no quantitative measurements were obtained for the area off Port Clinton, Ohio. Surface water temperature at Lorain, Ohio (60 km east of Port Clinton) was 14.5°C and is considered representative for much of the southern shore under the prevailing onshore winds.

The multiband aircraft camera observations are presented in Figure 3 as strip mosaics. An abrupt contrast reversal is evident either side of 0.7µm between the ERTS-simulated MSS bands "5" and "6" (0.6-0.7µm and 0.7-0.8µm, respectively). The material that absorbs shortwave energy in the visible wavelengths reflects incident radiation in the near-IR wavelengths. Due to the strong solar absorption in the visible wavelength, it was not surprising to find an associated higher surface temperature in the thermal-IR data (Figure 4) obtained simultaneously. The near-surface nature of this material is made evident by small boat wakes normal to the streamer that interrupt the visible, reflected-IR and thermal-IR features.

A portion of the ERTS-1 MSS digital data was redisplayed on a Digital Muirhead Device (DMD) at the National Environmental Satellite Service. The DMD utilizes a high intensity modulated light source to generate high quality transparencies from a digital input. Use of the DMD makes it possible to enhance the lower radiances characteristic of water. Through the use of the DMD, considerable information frequently can be extracted from MSS data that appear as a uniform black tone in the original unenhanced ERTS imagery. DMD-reprocessed, 14-nautical-mile wide, north-south swaths of the original MSS-5 and MSS-6 imagery are shown in Figure 5. The "chip" begins at Point Pelee on the north shore of Lake Erie and terminates at

The anticyclonic gyre in the vicinity of Point Pelee is a typically observed circulation feature for the location (see Chapter 7).

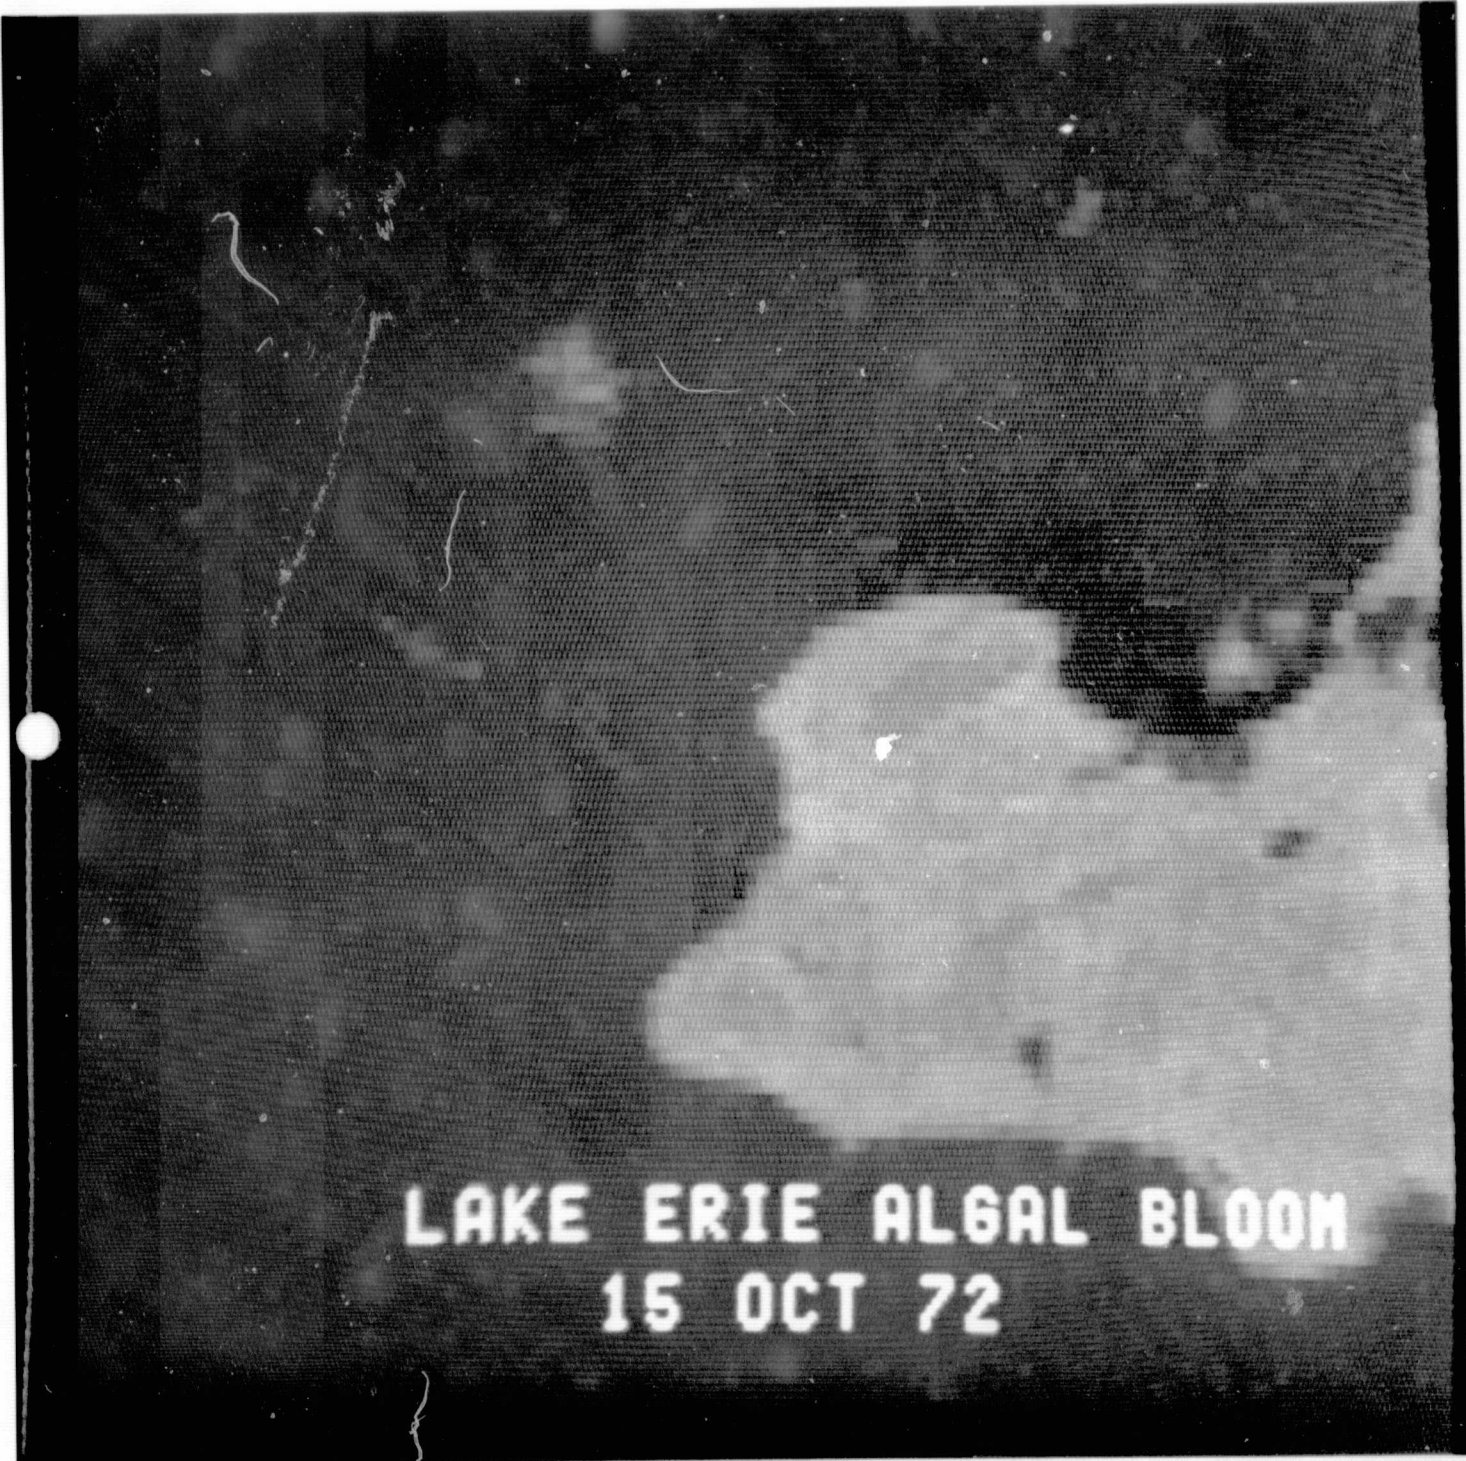

PRECEDING PAGE BLANK NOT FILMED

Marblehead, Ohio, just north of Sandusky. Although the 15 October ERTS-1 imagery barely covered the phenomenon observed in Figures 2 and 4, the high reflectance of the westernmost portion can be seen in MSS-6 immediately west of Kelleys Island. A large reflective region appears in MSS-6 to the east of Pelee Island. It is suspected this represents lesser algal concentrations, for no similar patterns are observed in MSS-5. It is well known that summer algal blooms make regular appearances in Lake Erie, particularly in the area around the islands (Casper, 1965).

Computer compatible ERTS-1 tapes were processed on General Electric's Multispectral Analyzer - "Image 100" - to see whether a classification training could be established for the algal blooms. A test site was chosen to the west of Kelleys Island where the algal bloom was seen both from the aircraft and ERTS-1. Figure 6 shows the full resolution ERTS data processed on the "Image 100". A fluffy cumulus cloud lies north of (above) the algal streamer that appears as a red line. Table 1 shows the "training" performed for the display in Figure 7. Basically, MSS-7 was used as a water identifier (low values = water) and MSS-6 as the algal bloom detector. Although no surface truth existed to allow us to be more definitive regarding concentrations, Bukata et al. (1974) have demonstrated a correlation of surface biomass with MSS-6. Applying this test site training we were able to produce a "classification" of the entire ERTS-1 scene for 15 October 1972. The resulting image is shown in Figure 8. For this display a 6-line x 6-spot ERTS sampling was used to provide a one-picture overview. Sampling every 6th line ensured that we always display data from the same detector of the six detectors used in ERTS-1, thereby eliminating the troublesome variability in calibration found between detectors. The training display presented in Figure 8 was altered only slightly and appears in Table 2. Although the MSS-6 values are lower in the overview classification there are probably fewer "false alarms" for

Figure 6. "Image 100" false-color enhancement of ERTS-1 MSS-6 data for Kelleys Island test site. Algal streamer lies left of the island. 15 October 1972.

algae as only MSS-7 values of 1 count were permitted. Evidently Sandusky Bay (south of Kelleys Island) and the eastward coastal current along the Ohio shoreline are teeming with algae. Despite considerable cloud cover the classification is not confused by this obscuration. Finally, the eastern portion of Lake St. Clair is classified as a rich source of surface algae along the upper left edge of the ERTS-1 view.

On 9 September 1972, a little more than one month prior to the October observation, ERTS-1 imagery showed another suspected distribution of algal material in Lake Erie. The DMD enhancement of MSS-5 and MSS-6 are shown in Figure 9. This swath is 31-km wide and Point Pelee is at the left side of the strip. The wavelike structure is presumed to be related to the Lake Erie internal seiche and shows the pulse-like nature of the alongshore current moving eastward through the islands and around Point Pelee. The algal streamer appears to originate immediately east of Pelee Island. The streamer extends nearly 46 km and shows widths varying from 0.2 to 2 km. Additional color enhancements are provided of MSS 4, 5 and 6 using "Image 100" in Figures 10, 11, and 12, respectively. Again GE's "Image 100" was utilized to classify the algal bloom in Lake Erie. The training method was similar to the one discussed above. Table 3 indicates what digital information went into each color displayed in Figure 13. This is a 4-channel training on all pixels in the gyre test area off Point Pelee.

The detector banding that appears in Figure 13 is an obvious detracting in the 5 line x 6 spot sampling presented in Figure 14. This demonstrates the need for better calibrations on future space systems. A 6 line x 6 spot sampling (Figure 15) recovers most of the information one would expect from the training above. It is assumed that the higher surface algal concentrations have been mapped by this process.

LAKE ERIE ALGAL BLOOM

9 SEP 72

The gyres off Point Pelee are enhanced. Algal material appears to be flowing out of the western basin of Lake Erie above Pelee Island and then eastward along the southern shoreline. The surprise from this classification is the apparently low concentrations in the Sandusky Bay area that became extremely high 5 weeks later (Figure 8). Although it is difficult to be quantitative with the MSS data there would appear to be greater surface algal concentrations (higher MSS-6 counts) during the 15 October algal bloom. A second surprise was an inference of a high level of biological activity off Erie, Pennsylvania in the right-hand half of the scene. Although research vessel data were available in this area of Lake Erie, unfortunately no surface chlorophyll or similar data were available.

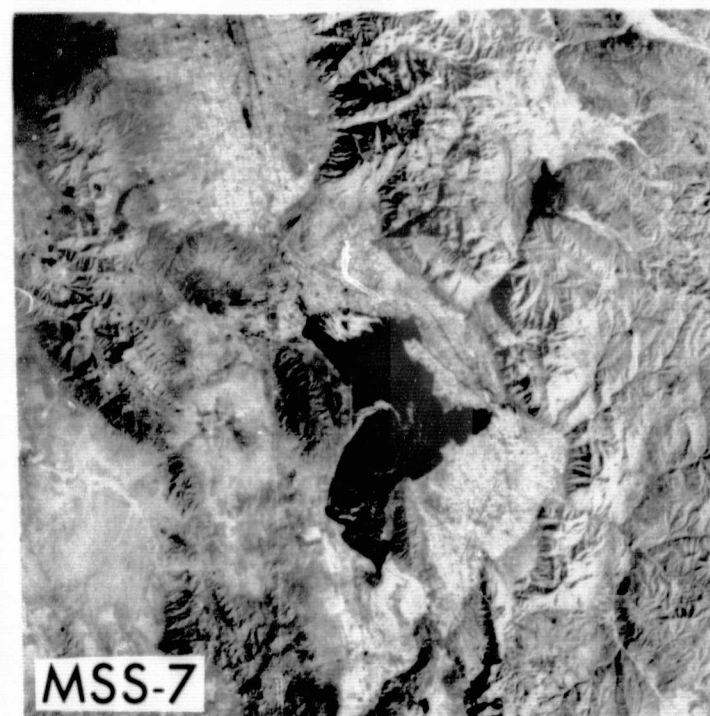

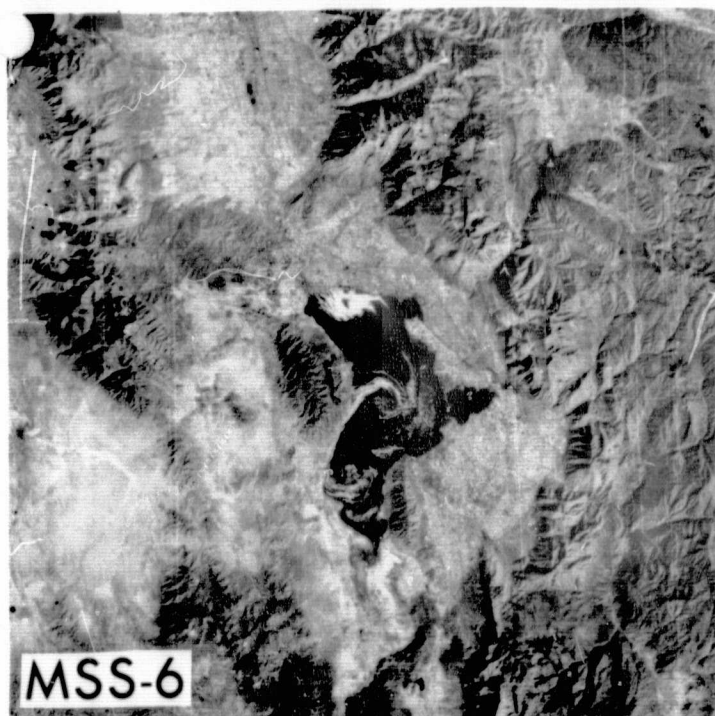

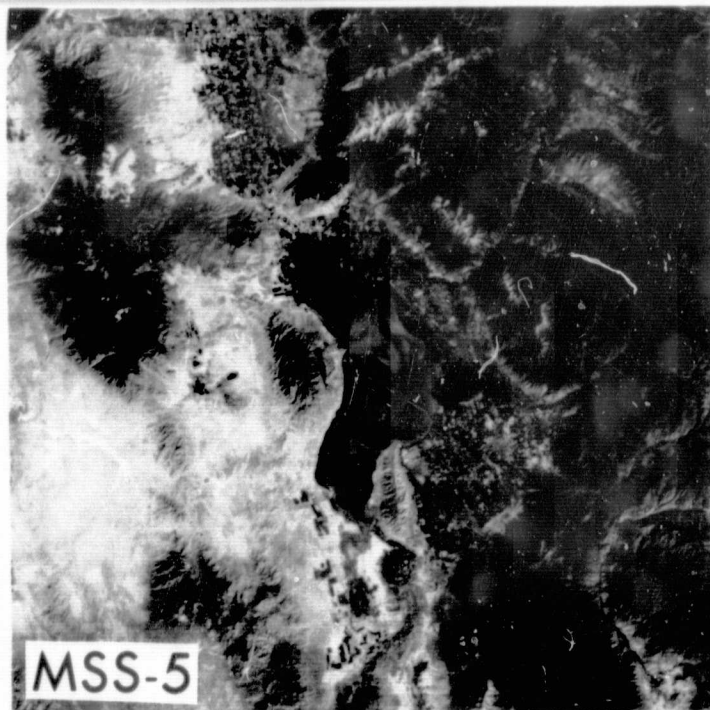

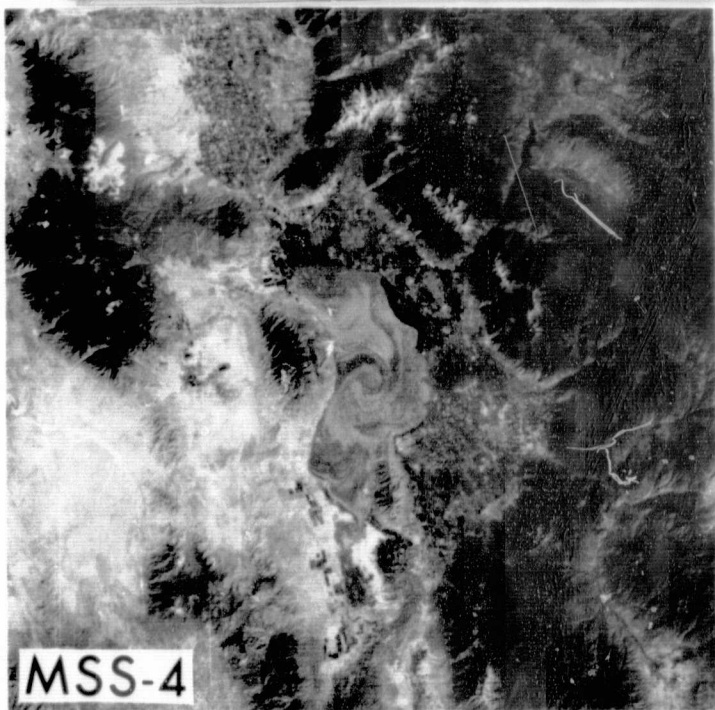

A much superior ERTS-1 observation of an algal bloom was obtained over Utah Lake on 12 September 1972. Figure 16 shows an anticyclonic gyre in this shallow (about 3-m deep) and highly eutrophic lake (PO_4 about 0.5 mg/l). The ERTS imagery shows a reversal in contrast for the gyre at $0.7\mu m$. The gyre itself covers a large percentage of the surface of this lake, which has a surface area of about $375 km^2$. Utah Lake is known for its high turbidity and summer algal blooms. Within one day of this satellite observation, a limnological cruise on Utah Lake revealed a massive, highly variable bloom of Aphanizomenon flos-aquae (White and Rushforth, 1973).

Discussion

Oceanographers and limnologists have observed that ERTS-1 imagery provides much detail in MSS-4 and -5, yielding information on circulation, biomass, and turbidity distributions (Maul, 1973). Charnell and Maul (1973) have discussed the light penetration expected in pure water for the four ERTS-1 MSS channels. Observed radiances, a function of both absorption and scattering in the water, are noticeably wavelength-dependent. In pure water, 50% light transmission will be observed over a depth of 10 m

Figure 16. 12 September 1972 ERTS-1 imagery of Utah Lake ($40^{\circ}10'N$, $111^{\circ}45'W$) where an algal bloom covers large portion of lake. MSS chips are approximately 50 km on a side and centered on Utah Lake.

REPRODUCIBILITY OF THE ORIGINAL PAGE IS POOR,

by MSS-4, 2.5 m by MSS-5, 0.5 m by MSS-6, and 0.2 m by MSS-7. In the "real world" of turbid water these depths are noticeably reduced. The strong absorbing characteristic of water for the near-IR wavelengths (greater than $0.7\mu\text{m}$) makes it possible to detect substances that are strongly reflective at these wavelengths when they are at or project above the surface of the water. The reflectances of such features diminish in the near-infrared (MSS-6 and MSS-7) whenever they are covered by even a thin layer of water. As an example, a pronounced reduction in reflectance has been observed when a thin layer of melt water covers ice (Strong et al., 1971).

Algal blooms, although not previously documented from space, have been seen and photographed from aircraft. Aero-infrared Ektachrome film has been used successfully to image periphyton in the Great Lakes (Noble et al., 1967). Chlorophyll detection in cropland is extremely useful to the remote sensing agronomist. Using multispectral techniques, he can infer such qualities as crop vigor, stage, moisture stress, and disease. The near-infrared reflectance from living plants increases rapidly between wavelengths of 0.70 and $0.75\mu\text{m}$ (Bressette and Lear, 1973). Whenever high concentrations of algal materials are found on a water surface they stand out dramatically against an otherwise dark background at these wavelengths. MSS-6 on ERTS-1 is well-suited for surface algae detection. If the algal bloom is thick and provides enough buoyancy to allow the upper surface to dry, the reflectance is sufficiently intense to be observed in MSS-7 imagery as well.

Algal blooms have been noticed during or immediately following calm periods accompanied by abundant insolation. Some blooms are highly toxic (e.g., red tides), whereas others attract fish with beneficial results. They are most notable in eutrophic lakes and in some coastal areas of the

oceans. Unfortunately the evolution of most algal blooms takes place over only a few days. This makes ERTS-1 a poor vehicle from which to monitor these events because of its repeat cycle of 18 days.

Concluding Remarks

Because the ERTS-1 MSS sensing was successful in observing the strong chlorophyll reflectance on Utah Lake, we are reasonably certain that the patterns seen in similar imagery over Lake Erie indicate the existence of an algal bloom there. Although no surface data have yet been found to corroborate this inference, past history indicates that blooms in this area are plentiful. A vigorously growing algal biomass is rich in chlorophyll and strongly reflects radiant energy in the near-IR bands. The dark green or brown color of this biomass is likely to cause the upper algal surface to appear darker at visible wavelengths and its warmth to cause it to appear brighter at thermal-IR wavelengths than the surrounding highly turbid coastal waters. Algal blooms can be expected to occur during periods of low surface winds, warm water conditions, and substantial insolation. These conditions preceded both the Lake Erie and the Utah Lake observations. Although most Great Lake algal blooms can be expected to be on a scale barely resolved by the ERTS-1 system, a careful interpretation and some judicious computer processing and image enhancement should reveal many algal bloom situations that would otherwise go undetected. Additional use of a multispectral analyzer permits rapid interpretation of an entire ERTS-1 scene and classification of several levels of near-surface biological activity. Not all algal blooms should be expected to yield high contrast features. It is for the less distinct growths that the computer is most necessary. Basic training algorithms can quickly be

applied to the entire data array for areal determinations and monitoring of algal concentrations.

Monitoring algal blooms and their distributions not only provides information on the quality of the water that supports them but also provides valuable data on the circulation of the water supporting the rich biomass.

WHITINGS

Whitings are defined as areas of milky-white water composed of calcium carbonate crystals (Bathurst, 1971). Portions of this chapter were first presented at the Ninth International Symposium on Remote Sensing of Environment in April 1974 at Ann Arbor, Michigan (Strong et al., 1974). Further findings are incorporated in this chapter. Additional studies are planned during the coming year. A "whiting event" presents truly an interdisciplinary phenomenon as geology, chemistry, biology, meteorology, and physical oceanography are involved.

INTRODUCTION

Satellite limnology received only scant attention until higher resolution sensors became available in 1972 (Strong, 1967; Sabatini, 1971; Strong and Baker, 1971). During that year the ERTS-1 and the NOAA-2 satellites were successfully launched. With the 80-meter multispectral resolutions of ERTS-1 and NOAA-2's Very High Resolution Radiometer (VHRR) 1-kilometer resolution, detailed satellite studies in coastal areas and in the Great Lakes have become possible.

Due to the orbit geometry and the narrow data swath (185 km wide) obtained along each ERTS-1 pass, coverage of the Great Lakes repeats every 18 days, beginning at the eastern end of Lake Ontario. Twelve days later it completes its Great Lakes' coverage over western Lake Superior. The data swath from NOAA-2 is ten times wider, with daily coverage from both visible and IR channels. The IR channel also makes nightly coverage possible. The ERTS-1 satellite transit is approximately 0930 local time, i.e., about 30 minutes after NOAA-2's passage over the same region. Frequently, this separation in coverage from ERTS-1 and NOAA-2

is considerably less than 30 minutes, greatly facilitating the integration of the ERTS-1 multispectral and NOAA-2 IR data sets.

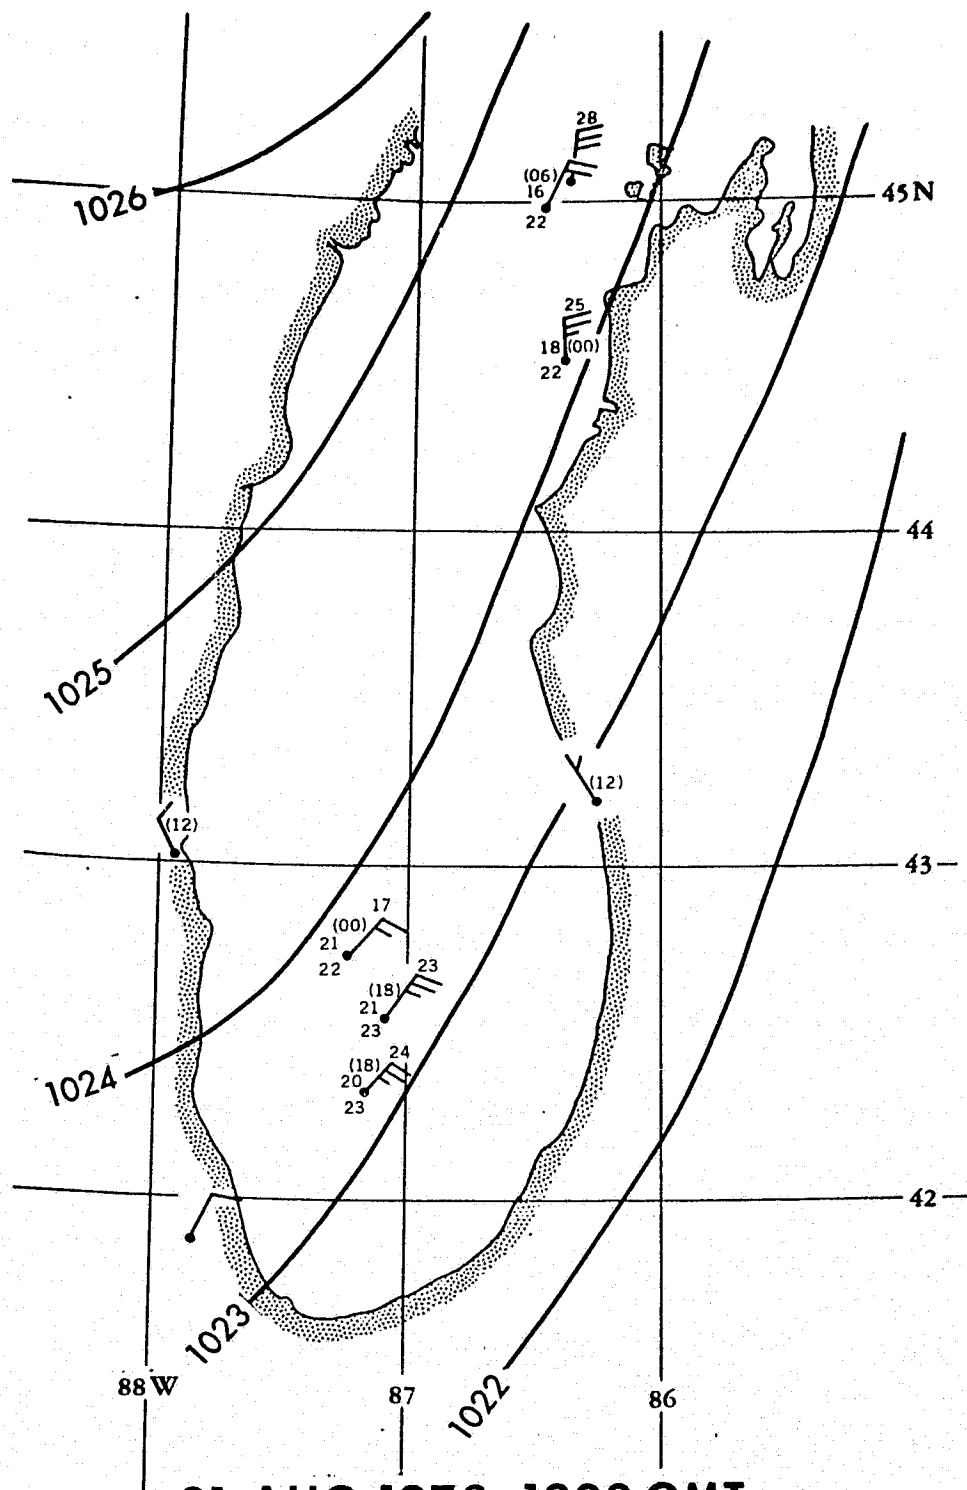

UPWELLING IN LAKE MICHIGAN

According to local Great Lakes sources, the summer of 1973 was an unusual one for Lake Michigan. Numerous and extensive upwellings occurred on both eastern and western shores. Since upwelling promotes mixing, an immediate consequence during the 1973 summer period was an improvement in water quality.

One of the more intense upwelling periods began on 20 August and continued for nearly a week. Along the eastern shore, from Frankfort, Michigan to Chicago, Illinois, water intake temperatures for all municipalities plunged from typical August levels of 20°C to less than 10°C. Standard meteorological data from nearshore stations indicated offshore winds were generally less than 5 m sec⁻¹, thus failing to forecast any possibility of major upwelling. However, several ship reports from southern Lake Michigan indicated surface wind speeds nearly three times those over land. Recently, additional reports have confirmed these indications of strong winds at the eastern shore (Hicks, 1973; USGS, 1973). Surface pressure ship and land weather observations are shown in Figure 17.

The evolution of the 20 August upwelling episode was monitored on five consecutive occasions by NOAA-2. During the morning transit of NOAA-2 no unusually cold water was in evidence along the entire eastern shoreline. By evening, however, thermal data from NOAA-2 (Figure 18) indicated that upwelling (lighter grey shades) was beginning immediately south and west of the three major points of land south of the Manitou Islands: Point Betsie, Big Sable Point and Little Sable Point. The 21 August morning

Figure 17. Surface weather for 21 August 1973 in the Lake Michigan region. Surface pressure (millibars) is from 1200 GMT observations. The time of ship and selected shoreline observations are indicated above station circle in parenthesis. Parameters included beside station circle are: air temperature (upper) and water temperature (lower) immediately to the left of the station; wind direction and velocity (reported speed, in knots, appears above "feathers"---one "feather" = 10 knots).

imagery from NOAA-2's VHRR-IR channel (Figure 19) shows upwelling that has enveloped the entire Michigan shoreline south of the Manitou Islands. The analysis in Figure 20 shows the resulting surface temperature field obtained from this VHRR data. A spatial averaging of the VHRR data over a 4-km square is necessary to remove a small amount of high frequency noise.

Figure 21 presents the visible (red) channel information from the VHRR on 21 August. Sunlint (see Chap. 5) is evident over Lake Michigan and affects the VHRR-VIS imagery along the eastern (right) synchronization line (white) during summer months when the solar elevation is high. Despite the contamination from sunlint, features evident in the VHRR-VIS over Lake Michigan are also visible in ERTS-1 imagery acquired one hour earlier (Figure 22).

In Figure 22 the MSS-4 channel reveals considerable turbidity in the surface waters of nearly the entire lake; the turbidity is much less obvious in the MSS-5 channel. This effect presumably indicates increased turbidity below the water surface rather than at the surface. This follows from the fact that the radiant energy in the red channel (MSS-5) comes from only the upper few meters of the water and the green channel (MSS-4) is effective for turbidity observations to depths on the order of 10 meters. One area displaying an exception to this is along the shoreline from Muskegon to Benton Harbor; here the turbid water undoubtedly relates to erosion along the high bluffs, which have been threatened by the higher Great Lakes water levels of the last two years.

Displaying CCT data from ERTS-1 for 21 August on the "Image 100" permits a more quantitative understanding. Sampling of the ERTS-1 scene over 6 spots every 6 lines provides a useful overview. Banding is not as

troublesome when observing these very turbid conditions in the visible portion of the spectrum. Banding has been most noticed when trying to use the near-IR data in MSS-6 or -7 (Chap. 2, Figures 14 and 15). Figure 23 is a color image using blue and green light on MSS-4 and red light on MSS-6 data. It is remarkable to see how much of the surface water area is affected. Figure 24 categorizes increasing levels of reflectance in MSS-4 where the other three-dimensional multispectral information for each pixel has a low value of reflectance. Table 5 shows the classification employed. Red is used to designate nearshore turbidity. Higher reflectance levels in MSS-5 are included for this signature and typify the erosion of the bluffs seen near Benton Harbor.

On the following day, 22 August, the VHRR-IR imagery revealed a somewhat enlarged upwelling strip along the coast (Figure 25). The analysis shows lower water temperatures over the central lake and along the shoreline (Figure 26). Ship weather observations revealed winds that were more easterly but continuing strong (around 10 m sec^{-1}).

A similar episode occurred on Lake Michigan beginning on 26 July. This upwelling was observed by ERTS-1 on 3 August, eight days later, when the phenomenon was in its final stages. Considerable turbidity can be seen again (Figure 27), but the MSS-4 levels of reflected radiation in the green band are much lower than observed by ERTS-1 on 21 August. For comparison the VHRR-IR image from NOAA-2 is shown in Figure 28. The same classification scheme used in Figure 24 and Table 5 has been employed in the color image in Figure 29. Only the third CCT for the Chicago scene has been processed on the "Image 100." The strip includes the Gary, Indiana shoreline. Reflectances observed on 3 August appear to be nearly identical to those observed on 21 August, although the latter

case presents greater contrasts.

In all cases water intake temperatures confirmed the intense upwelling along the eastern shoreline. Several locations reported temperatures below 10°C during the maximum upwelling. Standard chemical analyses performed on the raw water from these intakes (Muskegon, Grand Rapids, South Haven, Benton Harbor, St. Joseph, and Chicago) indicated no abnormalities. Values of pH dropped from typical epilimnetic readings of 8.0 to 8.5 to slightly below 8.0 as cold and slightly more acidic hypolimnetic waters were drawn from deep in the lake's interior. Turbidity levels were not in excess of those expected, peaking while the wind blew onshore during the 20th, and dropping when the winds blew offshore on the 21st. The lowest surface temperature found was that observed during the night of the 21st by the University of Michigan research vessel MYSIS, viz. 9°C just off Benton Harbor.

DISCUSSION AND CONCLUSIONS

Combination of ERTS-1 and VHRR-IR data allow one to make numerous interpretations of surface current under this extreme upwelling condition. Among such features are river plumes entering Lake Michigan in the upwelling area seen in Figures 22 and 27 that appear dark in contrast to the "whiting" effect of the lake water. After these plumes enter the lake they veer abruptly to the left (south) parallel to the shoreline. Secondly, darker areas in the ERTS-1 image are presumed to be regions of sinking or downwelling. For the most part these vertical circulations are found on the downwind shore across the lake. A rather large area of less milky water is seen off Chicago. This region would be expected to receive maximum water elevations (pile up) from the southwestward wind stress. In this

area, sinking water is depressing the main thermocline of the lake.

Thirdly, eddy circulations may be seen in the lee of headlands along the eastern shore, where some of the coldest surface waters are found. Finally, an eddy in the middle of the southern Lake Michigan basin is characterized by the warmest surface water observed on 21 August (Figure 20). Circulation of this large-scale feature is clockwise. Sinking would also be expected to accompany this unexpected circulation and may partially explain why some of this water is darker in the ERTS-1 imagery (Figure 22).

From the "Image 100" results (Figs. 24 and 29) a careful breakdown of the whiting is revealed. Similar structure and signature is observed for the 3 August and 21 August observations. The multispectral classification is both concentration and depth dependent and therefore not complete, as additional data are needed to separate these parameters. If all of the chemical precipitation is found to occur at a single level the classification becomes one of concentration (or vice versa).

From the 1973 observations it is our hypothesis that upwelling initiated the milky water phenomenon of August 1973. Cold upwelling waters and considerable mixing of the upper epilimnetic waters would trigger extensive phytoplankton development. Divers in Grand Traverse Bay noticed an abundant phytoplankton population at this time (L. Somers, 1974). These processes result in the removal of CO_2 from the surface waters and force a precipitation of carbonate ($\text{CO}_3^{=}$) with an appropriate anion, most probably calcium (Ca^{++}).

Ayers et al. (1967) have reported several instances of widespread milky water in Lake Michigan. In August 1966 observations conducted by the University of Michigan indicated Secchi disc readings reduced from

6-14 m, which are typical of mid-lake, to 2-4 m. No conclusive results came from their study, but they strongly suspected the milky conditions were the result of the precipitation of calcium carbonate from the surface waters.

The resulting late-summer die-off of deep-water shrimp, Mysis relicta, observed by Ayers et al. (1967) was presumed to be related to the presence of the milky water. A reoccurrence of this kill has not been reported in 1973.

The 1972-73 ice season on the Great Lakes was unusually short due to mild winter temperatures. A siege of cold Arctic air during mid-February succeeded in producing a short period of nearly complete ice coverage on Lake Erie; however, this thin cover deteriorated rapidly later in the month, leaving the surface nearly ice-free during the remainder of the winter.

Whenever cloud cover permitted, the operational NOAA environmental satellite, NOAA-2, was able to record valuable information on the surface temperature of the lakes and, when ice was present, the areas and amount of coverage. It was observed that even during light winds, a change in the direction of this wind can drastically and rapidly alter the ice distribution and concentration.

Special attempts have been made to assure the acquisition of VHR data at the National Environmental Satellite Service whenever the Earth Resources Technology Satellite (ERTS-1) overflies the region every 18 days.

USING SATELLITE IMAGERY TO MONITOR ICE COVER

Several VHR illustrations are provided that show ice conditions, primarily in Lake Erie, during (1) freeze-up, (2) total ice cover, and (3) thaw. Nearly all imagery is derived from visible channel data because the thermal data have not been specially displayed for the small range of temperatures encountered. Several ERTS-1 images are presented for comparative purposes.

Freeze-up

On 29 January 1973 an exceptional VHR-VIS view of Lake Erie was obtained; a portion of this image is shown in Figure 30. A typical winter scene prevails. On this cold morning (-10°C at Cleveland) the instability

Figure 30. 29 January 1973. 0900 EST NOAA-2 VHRR-VIS image of Great Lakes at initiation of freeze-up on Lake Erie. Note lake-effect cloudiness extending downwind from lake moisture sources.

REPRODUCIBILITY OF THE ORIGINAL PAGE IS POOR.

of cold air over warmer waters is made evident by "lake effect" lines of stratocumulus carried downwind from the lakes. One line, initiated by Lake Huron to the north, is especially prominent over Lake Erie and extends from Cleveland to Wheeling, West Virginia and the Appalachian Mountains. Numerous snow showers were observed to be embedded in this line of convective cloudiness. The ice that had first been detected on 13 January in both ERTS-1 and NOAA-2 imagery had melted, so all that is seen on 29 January is a small floe between Pointe aux Pins and Long Point just off the Canadian shoreline. Cloud cover prohibits any detection of ice in the island area off Sandusky, Ohio, although it is likely that some ice remains there.

Cold Arctic air again moved into the Great Lakes region in early February. Ice growth was dramatic, especially around 14 February. Figure 31 shows the VHRR-VIS imagery on this day and affords a nearly cloud-free view of all of the Great Lakes except Lake Superior. New ice in central Lake Erie is not nearly as reflective as that in Whitefish Bay, Georgian Bay, or Saginaw Bay where thickness and snow cover enhance surface reflectance (McClain, 1973). A windrow of ice can be seen near the center of southern Lake Huron.

Total Ice Cover

By 17 February, three days later, sustained "subzero" ($^{\circ}\text{F}$, -18°C) weather produced nearly total ice coverage on Lake Erie. The VHRR-IR imagery is shown in Figure 32 (no VHRR-VIS is available). Air temperatures along the shoreline of near -20°C provide large thermal contrasts over the ice for interpreting thickness. Ice acts as an insulator, so that as its thickness increases, its upper surface temperature more closely approaches the much lower air temperatures immediately over the air-ice interface.

Breakup and Thaw

On the following day (18 February) 10-kt southwesterly winds drastically altered the ice pattern. In Figure 33, VHRR-VIS imagery shows large cracks, often approaching 5- to 10-km wide, that have developed in the ice cover.

ERTS-1 imagery was acquired over Lake Erie on both 17 and 18 February. ERTS-1 obtains four-channel, 100-meter resolution visible imagery of a given Earth location every 18 days. This makes it possible, at times, to compare the 0.6-0.7 μ m imagery of NOAA satellites and ERTS. The ERTS-1 images in Figures 34 and 35 should be compared with the NOAA images in Figures 32 and 33, respectively. Ice-movement vectors were obtained by locating ice features seen in the overlap area of the consecutive-day ERTS-1 observations. This analysis is presented in Figure 36. Many of these features, of course, are unresolvable in VHRR imagery, but the large ice features will permit the production of ice motion charts for cloud-free periods.

Break-up and thaw proceeded at a rapid rate during March. By 27 March no ice of any consequence remained. The VHRR-VIS image shown in Figure 37 attests to this condition. The lake is extremely turbid following recent rains and high winds. A VHRR-IR image coincident with Figure 37 is presented in Figure 38. At this time of year all water surfaces in the Great Lakes are very uniform in thermal expression (the water temperatures are within two degrees of 2°C).

CONCLUSIONS

It has been demonstrated that NOAA-2 VHRR imagery can permit an accurate ice cover chart to be made of the Great Lakes, provided cloud cover is not persistent. Resolutions of 1 km appear adequate not only for assessing ice coverage and condition but also, when available on a day-to-day basis, charting ice motions that result from changing wind and current conditions. Snow cover enhances the ice cover as seen from space, and may

allow further judgments to be made on the age and thickness of the ice. Use of the IR data permits nighttime observations to augment the daytime observations. Furthermore, the availability of calibrated information will provide valuable surface temperature information. During cold periods this thermal measurement could be useful for relating to thickness and condition of the ice.

Although the 1972-73 ice year on the Great Lakes was a rather brief event, use of VHRR data for monitoring Great Lakes ice conditions will continue, and we expect it will increase substantially during succeeding winters. Those with shipping and coastal interests should expect to benefit from the new perspective on our environment. Use of ERTS-1 imagery is warranted in specialized circumstances where higher resolutions are required. However, daily coverage is the most critical weapon for ice monitoring in the Lakes. Further ERTS-1 ice and snow studies are available in another ERTS-1 Final Report from NOAA (Wiesnet, McGinnis and McMillan, 1975).

ERTS-1 imagery can be useful, as demonstrated, for monitoring ice motions in cloud-free areas where day-to-day sidelap is obtained. Although two successive clear days in the Great Lakes region are rare during winter, they become more probable if the Lakes become completely ice-covered in February. During late winter and spring ice-breakup, satellite observations are less frequented by cloudy conditions and may be extremely valuable to early shipping interests in the Great Lakes, provided imagery can be made available.

It was reported to NASA/GSFC in July and August 1973 that sunglint effects on surface waters could be expected in ERTS-1 imagery whenever solar elevations are in excess of 55° . These effects have been particularly evident under light variable wind conditions and make oceanographic/limnologic ERTS-1 work much more difficult, especially since clear sky (needed for satellite observation) and light winds tend to occur simultaneously. Furthermore, it was suggested at that time that several perplexing scenes, some of which had been discussed at recent conferences, could easily be explained using Cox and Munk (1954) data that had been modeled by NOAA for a satellite's perspective (Strong, 1972; Strong and Ruff, 1970; and McClain and Strong, 1969).

Although the true horizontal specular point (center of the sunglint) lies well outside the ERTS-1 imagery, the wind-roughened surface produces wave facets that are able to direct glint onto the MSS detectors. As the wind speed increases, this condition becomes more probable and the ocean surface appears brighter at greater and greater distances from the specular point. As discussed by Levanon (1971), this surface reflectance is best observed at red and reflected (near) IR wavelengths. The effects are best observed in MSS-6 and -7 (if properly enhanced) because sub-surface color differences are not apparent at these near-IR wavelengths.

Figure 39 shows an ERTS-1 image of Lake Michigan on 16 July 1973. MSS-5 and -6 are shown to illustrate the need for multispectral data in water color research, especially when solar elevations are high. Dark areas along the shoreline are particularly apparent in MSS-6 (right).

*The authors are indebted to Mr. I. Ruff for much of the modeling work.

Winds for this period were northeasterly, thus putting the nearshore waters in a wind shadow. Reported wind speeds ranged from calm to 5 m sec^{-1} . The NOAA-2 VHRR-VIS image, Figure 40, acquired soon after the ERTS-1 observation, provides an expanded perspective with the horizontal specular point nearly coincident with the Lake Michigan shoreline. In Figure 40, we observe that the southern area of this wind-shadowed darker water seen by ERTS-1 (Figure 39) reverts to a more brilliant near-specular reflection. Based on the Strong and Ruff (1970) model and similar work using time-lapse pictures from ATS (McClain and Strong, 1969), a case is easily made that the dark water in Figure 39 and the coincident bright water areas in Figure 40 are free of capillary waves. Simply stated, the surface is smooth because no wind stress reaches the interface.

The sunglint model adapted to satellite use (Strong and Ruff, 1970) has been further refined to provide definitive reflectances to overlay ERTS-1 imagery. Reflectance values are calculated as percentages of the incoming solar radiation under specified wind speeds without including any intervening atmosphere. The 16 July NOAA-2 VHRR-VIS image in Figure 40 has been overlain with an expected brightness distribution for calm winds and 5 m sec^{-1} winds in Figures 41 and 42, respectively. A latitude/longitude grid is also included. The observed reflectances in Figure 40 agree qualitatively with the predicted calm water results (Figure 41) near the eastern shoreline of Lake Michigan and the rough water results (Figure 42) away from shore.

A similar overlay series has been constructed for the ERTS-1 scene of Lake Michigan (Figure 39). Here we present brightness isolines calculated for windspeeds of 0, 2, 5, and 10 m sec^{-1} in Figure 43, 44, 45, and 46, respectively. It should be mentioned that no whitecap brightnesses

have been incorporated into this sunglint model. Above 5 m sec^{-1} some allowance should be made for additional reflectance from whitecaps.

It can be readily demonstrated that nothing is sacred regarding a threshold solar elevation below which no sunglint effects are possible. An extremely strong offshore wind can undoubtedly impose lee effects on the roughness generated in the small-scale wave field permitting the observation of variable sunglint features when solar elevations lie well below 50° on ERTS-1 images. It appears that solar elevations greater than 50° to 55° are sufficient to cause considerable brightness anomalies when wind speeds and associated roughnesses approach the calm-rough surface transition.

Sunglint wind-generated features are evident in the following ERTS-1 scenes that are chosen as representative samples:

28 July 1972	Rhode Island Sound
14 October 1972	Lee of the Antilles
28 July 1972	Monterey Bay
7 July 1973	Off Delaware Bay

It should be obvious that sunglint and its contaminating effects on water color observations from space must be recognized. Any dedicated satellite water-color mission must utilize a pointing sensor that is capable of looking away from the sunglint. Despite the more brilliant sunglint observed during a noon orbit it is possible to look away from the sunglint and observe ocean waters under high solar elevations without any sunglint contamination (Strong, 1972). Thus it would appear that a near-noon orbit would be optimum for ocean color and sunglint (wind speed/roughness) observations if provision can be made to avoid the glitter area.

During spring and fall months a good relationship is frequently observed between Great Lakes' surface water color and temperature. This relationship is probably best developed late in the spring when the lakes are warming rapidly and contributions from surface runoff are high (Wiesnet et al., 1975). NOAA-2 satellite VHRR data are presented in selected cases where ERTS-1 imagery is coincident with the thermal-IR from VHRR.

Although little surface temperature structure was evident on 27 March 1973 (Figure 47) in the NOAA-2 VHRR analysis, water color was abundant (Figure 48). The NOAA-2 VHRR data have been averaged over a 4-km grid to remove some high spatial frequency noise in the system (Strong, 1974). The resulting reduced resolution makes color/temperature correlations difficult under these nearly isothermal conditions. The VHRR temperature resolution is slightly better than 1°C.

One can detect a warmer turbid Detroit River effluent. VHRR data show surface temperatures in excess of 3°C. This is also true for the nearshore areas in Lake St. Clair. Only a slight indication of warmer (2-3°C) water is found along the southern Canadian shoreline of Lake Huron where waters were extremely turbid also (Figure 48).

By late April the lakes have progressed well into their warming cycle and reveal significant temperature patterns, particularly in nearshore surface waters. On 29 April 1973 ERTS-1 acquired imagery along its Buffalo swath. This nearly cloud-free Great Lakes pass provides turbidity information for Lakes Erie and Ontario as seen in Figure 49. The VHRR image showed warmer water emanating from the Niagara River and elsewhere along the southern shore of Lake Ontario. These areas are the turbid regions in the ERTS-1 imagery. A VHRR temperature analysis overlay in Figure 50

demonstrates this good correlation and the obvious need for ERTS thermal-IR data on future satellites. The same correlation may be observed between thermal and turbidity data in Lake Huron on 20 May 1973 (Figures 51, 52, and 53).

A summer upwelling in Lake Michigan discussed in Chapter 3 reveals a more complicated relationship between thermal and turbidity data. The warmer mid-lake waters (ca. 20°C), away from the upwelling, support the green milky waters that are believed rich in phytoplankton and calcium carbonate. This temperature/color relationship parallels the observed spring color/temperature relationship. However, along the Michigan shore in the southern portion of the lake, surface turbidity at a very high level can be observed where waters are quite cold (ca. 10°C). This reverse relationship is expected during fall and early winter, but it was difficult to observe by ERTS-1 and NOAA-2 because of persistent cloud cover.

Case Studies

The ERTS-1 system has added a new dimension to physical oceanography. Conditions permitting, one is now able to chart circulation patterns using natural tracing material borne in the surface waters. These colorants are chiefly turbidities from riverine effluents consisting of sediments, pollutants, algae or natural dyes. Occasionally chemical precipitations are noted (see Chapter 3); these too are employed in this chapter as circulation tracers. Synoptic oceanographic or limnologic studies have always been difficult if not impossible from shipboard. Circulation patterns are constantly being altered by changing meteorological influences. Observing tracer features from space, a nearly instantaneous "snap shot" provides circulation information that should relate to the present and near-past meteorological forces.

Ayers (1959) has developed an empirical relationship that takes into account the large time lag between the onset of a given wind condition and the response of the water circulation to this wind. A complete response of current to the wind takes many hours, or even several days. The resultant effective wind stress relationship developed reduces the forcing influence of the previous day by one-half that of the given day. In this report we have chosen to utilize three days of wind data prior to each ERTS-1 scene. In addition, to better emphasize the 24-hour period immediately prior to the ERTS-1 data, we have represented the 6-hourly winds in a weighted resultant stress vector as follows:

$$\vec{w}_{(\text{day } 1)} = \frac{\vec{w}_{(-24)} + 2\vec{w}_{(-18)} + 3\vec{w}_{(-12)} + 4\vec{w}_{(-6)}}{10}$$

The subscript after each vector wind observation denotes observation time (hours) before noon of the day of the ERTS-1 observation.

A final vector resultant wind for the three-day period was obtained using the following formula:

$$\vec{W} = \frac{\vec{w}_{(day\ 3)} + 2\vec{w}_{(day\ 2)} + 4\vec{w}_{(day\ 1)}}{7}$$

For a more rigorous relationship one needs to take into account additional parameters such as atmospheric stability over the water, wave condition, current locations as a function of the distance to shore, etc. (see Jones and Bellaire, 1962). Much of this fine tuning, however, is not too realistic with the present paucity of wind data. In this study, we have chosen, wherever possible, to use the U.S. Coast Guard weather observations from shore installations rather than inland sites. Although these winds may suffer some due to local anomalies in the wind field (e.g. lake breeze circulations) they are felt to be the most representative of true lake winds.

Circulation vectors have been extracted from each ERTS-1 scene using all natural or man-made tracers in the surface waters available to the analyst. As an illustrative example, the interested reader should compare the circulation derived for Lake Michigan under a resultant northerly wind (Figure 55a) with the whiting image in Chapter 3 (Figure 22). Although complex much of the analysis is straightforward when a trained interpreter is used.

Wherever possible the circulations inferred from the ERTS-1 data have been compared with past studies, empirical or theoretical, of surface circulation patterns in the Great Lakes. The five areas selected for intensive current depiction as a function of effective wind stress are:

Southern Lake Michigan

Southern Lake Huron

Lake St. Clair

Lake Erie

Lake Ontario

These areas were selected because they regularly display the high turbidities that are necessary to observe circulation from ERTS-1.

Charts were prepared for all cardinal and subcardinal resultant wind directions (i.e., N, NE...NW). Some ERTS-1 observations of currents under a few wind directions were not available during the study period (August 1972 to December 1973). Whenever more than one ERTS-1 observation was used in a given area, the currents presented are composites. Although most current charts are based on only one ERTS scene, if two scenes were available for a given resultant wind direction the observation under the stronger wind stress was generally used. It should be mentioned that circulation variations should be expected under weaker or stronger resultant wind stress from the same direction. It was chosen to concentrate primarily on the direction of the wind vector rather than vector magnitude in this report. Figure 1 shows the areas covered by any given ERTS-1 pass. The reader should be aware of the sunglint difficulty whenever the solar elevation exceeds 55° (see Chapter 5). Current interpretations are subject to errors under these conditions. Future studies should utilize a sunglint removal technique (e.g. MSS-6 minus MSS-5, Watanabe, 1974) for more credible results.

Southern Lake Michigan

The location of wind information used in preparation of the southern Lake Michigan current charts is shown in Figure 54. All locations referenced in the text are also identified on this base chart. Only incomplete wind data were available from the Milwaukee and Muskegon Coast Guard facilities. Table 6 presents a summary of ERTS-1 scenes utilized in

Figure 54. Wind station used for southern Lake Michigan (Dunne Crib - Chicago).

addition to resultant wind direction calculated from the above formula.

Additional coverage data are available in the Appendix (Table A2).

Northerly Winds - Figure 55a

The figure indicates the general surface circulation established by predominantly northerly light/moderate winds as derived from two cloud-free ERTS-1 passes (16 July 1973 and 21 August 1973). The latter pass was particularly useful because that date marked the occurrence of an extensive CaCO_3 precipitation that was especially evident in MSS-4 (see Chapter 3). The major features established by this wind regime are several large gyres and distinct alongshore currents. An east shore southward current extends from Little Sable Point to Michigan City, where it becomes deflected to the northwest to become part of the eastern boundary of a large counter-clockwise eddy off Chicago, first described by Ayers et al. (1958) and confirmed by Bellaire (1964). In this case, the eddy extends as far north as Waukegan. From Little Sable Point a branch of the east shore current flows southwestward and becomes incorporated in a second mid-lake counter-clockwise gyre. This corresponds to the eddy noted by Bellaire (1964) above the mid-lake sill between Milwaukee and Muskegon. A third eddy has a clockwise circulation and lies off Benton Harbor, Michigan, in the eastern part of the lake. This eddy has been previously observed (Ayers et al., 1958 and Bellaire, 1964), but here it is much smaller than reported previously. Along the Wisconsin shore at Milwaukee there may be a small nearshore clockwise eddy; it has been previously documented (Ayers et al., 1958), but the evidence in the ERTS-1 images indicates only that there is a southward current some distance offshore.

Northeasterly Winds - Figure 55b

Only one ERTS-1 pass was available for northeasterly wind conditions (17 July 1973), and only the Milwaukee area was sufficiently cloud-free

to allow mapping of the sediment distribution patterns. The outflow current begins along the Wisconsin shore at Sheboygan and flows southward. After several days of northeasterly winds, water is transported onto the west shore from Milwaukee to Gary and is piled up there; on the slope of this wind set-up, the water flows southward and northeastward (Ayers, 1959).
Easterly Winds - Figure 55c

On 11 March 1973, ERTS-1 passed over the southeast portion of Lake Michigan. It was evident from the sediment patterns observed that the east shore current flowed southward from Holland to Michigan City and then westward to Chicago. Off Michigan City is an apparent small flattened counterclockwise eddy, previously described by Ayers et al. (1958) under a similar easterly wind regime. North of Benton Harbor a branch from the east shore current flows southwestward toward the middle of the lake, presumably to become part of the large clockwise gyre located along the shore between Holland and Benton Harbor. This is the same clockwise gyre discussed under Northerly Winds and documented by Ayers et al. (1958) and Bellaire (1964).

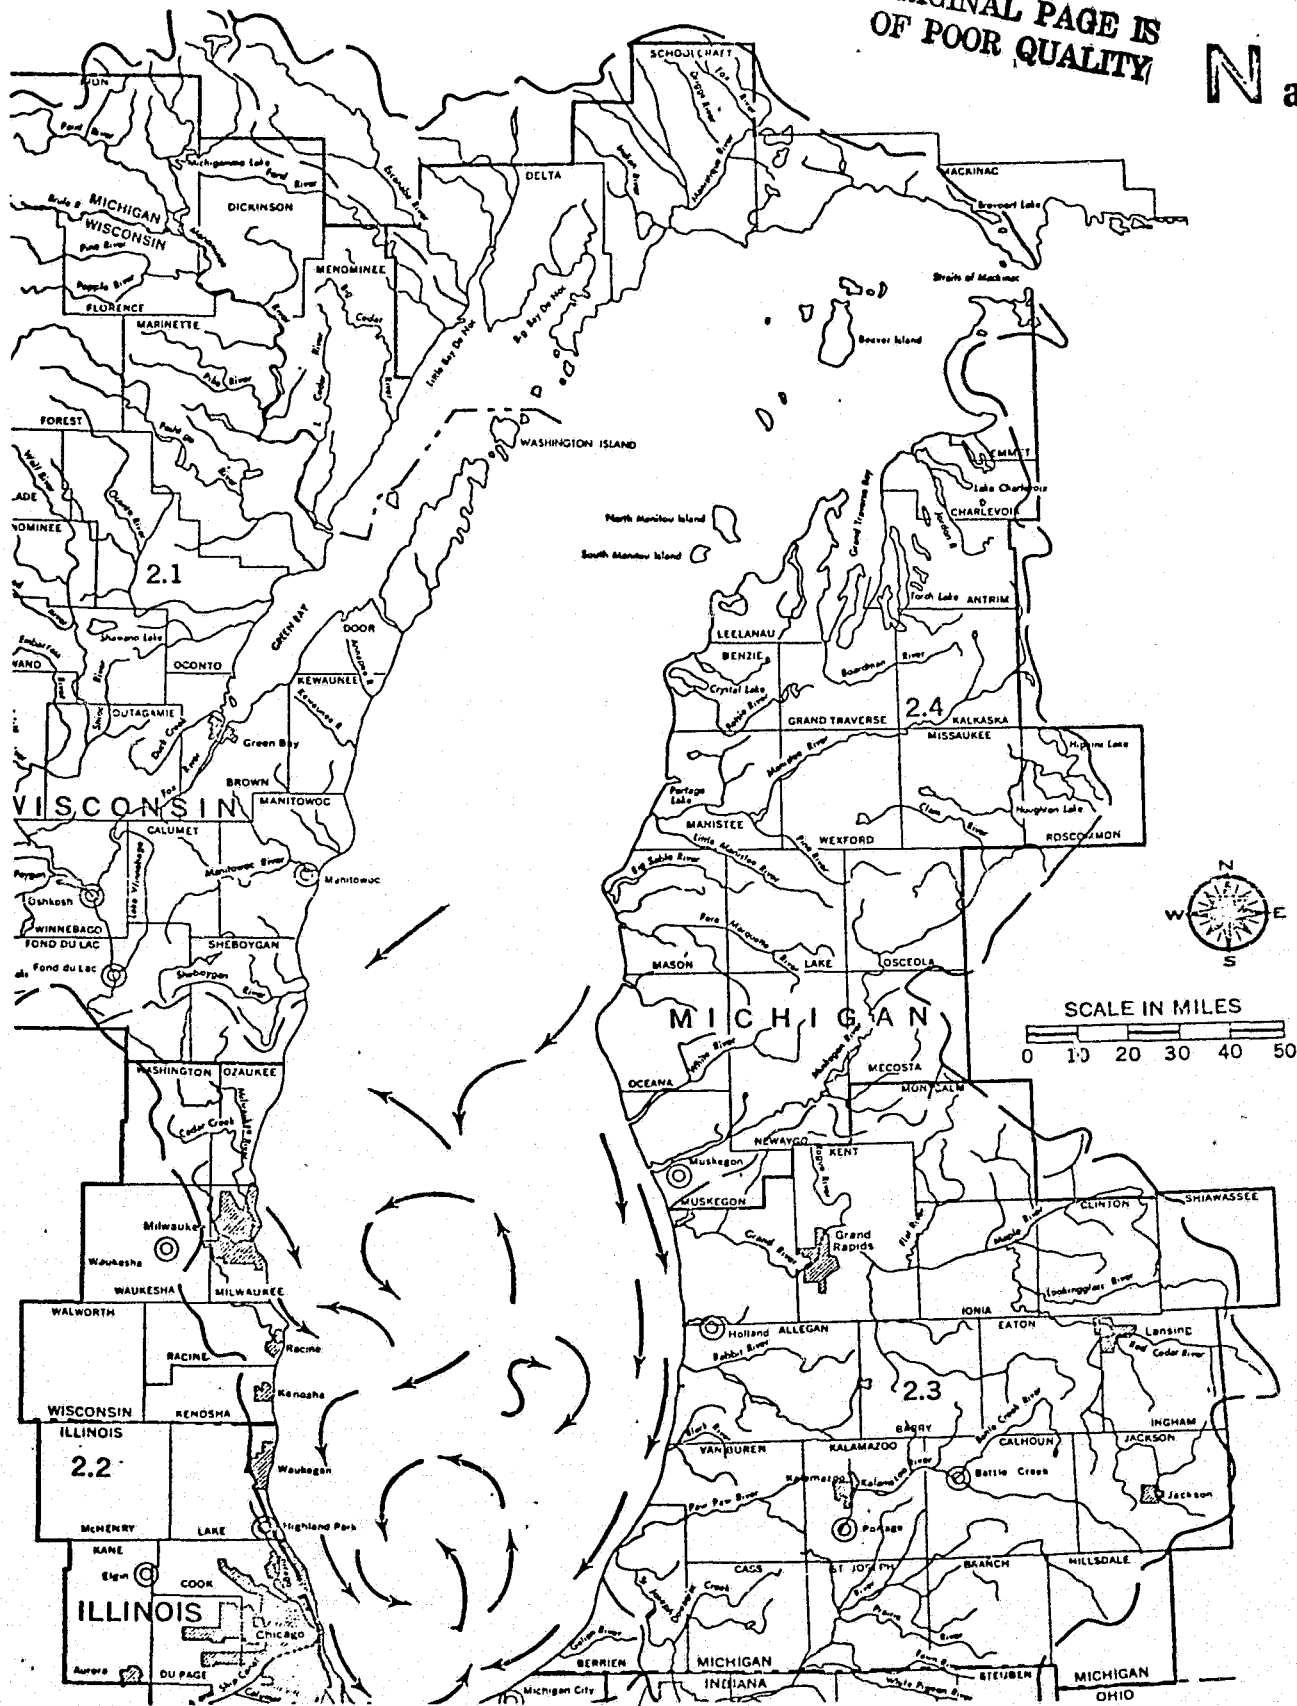

Southwesterly Winds - Figure 55d

The current diagram is a composite analysis of two ERTS-1 passes (10 June 1973 and 14 October 1973). The major feature evident in the figure has already been discussed--the large clockwise gyre along the east shore between Benton Harbor and Holland. The southward current along the east shore is very narrow under these southwesterly winds and it was not observed to extend south beyond Benton Harbor, where it turns westward to become incorporated into the eddy. According to the sediment distribution patterns, water is flowing northeasterly directly offshore from Chicago to the center of the lake. This apparent major upwelling has not been previously documented; Ayers et al. (1958) and Bellaire (1964) have described fully-developed gyres at this location. Offshore currents are indicated all along

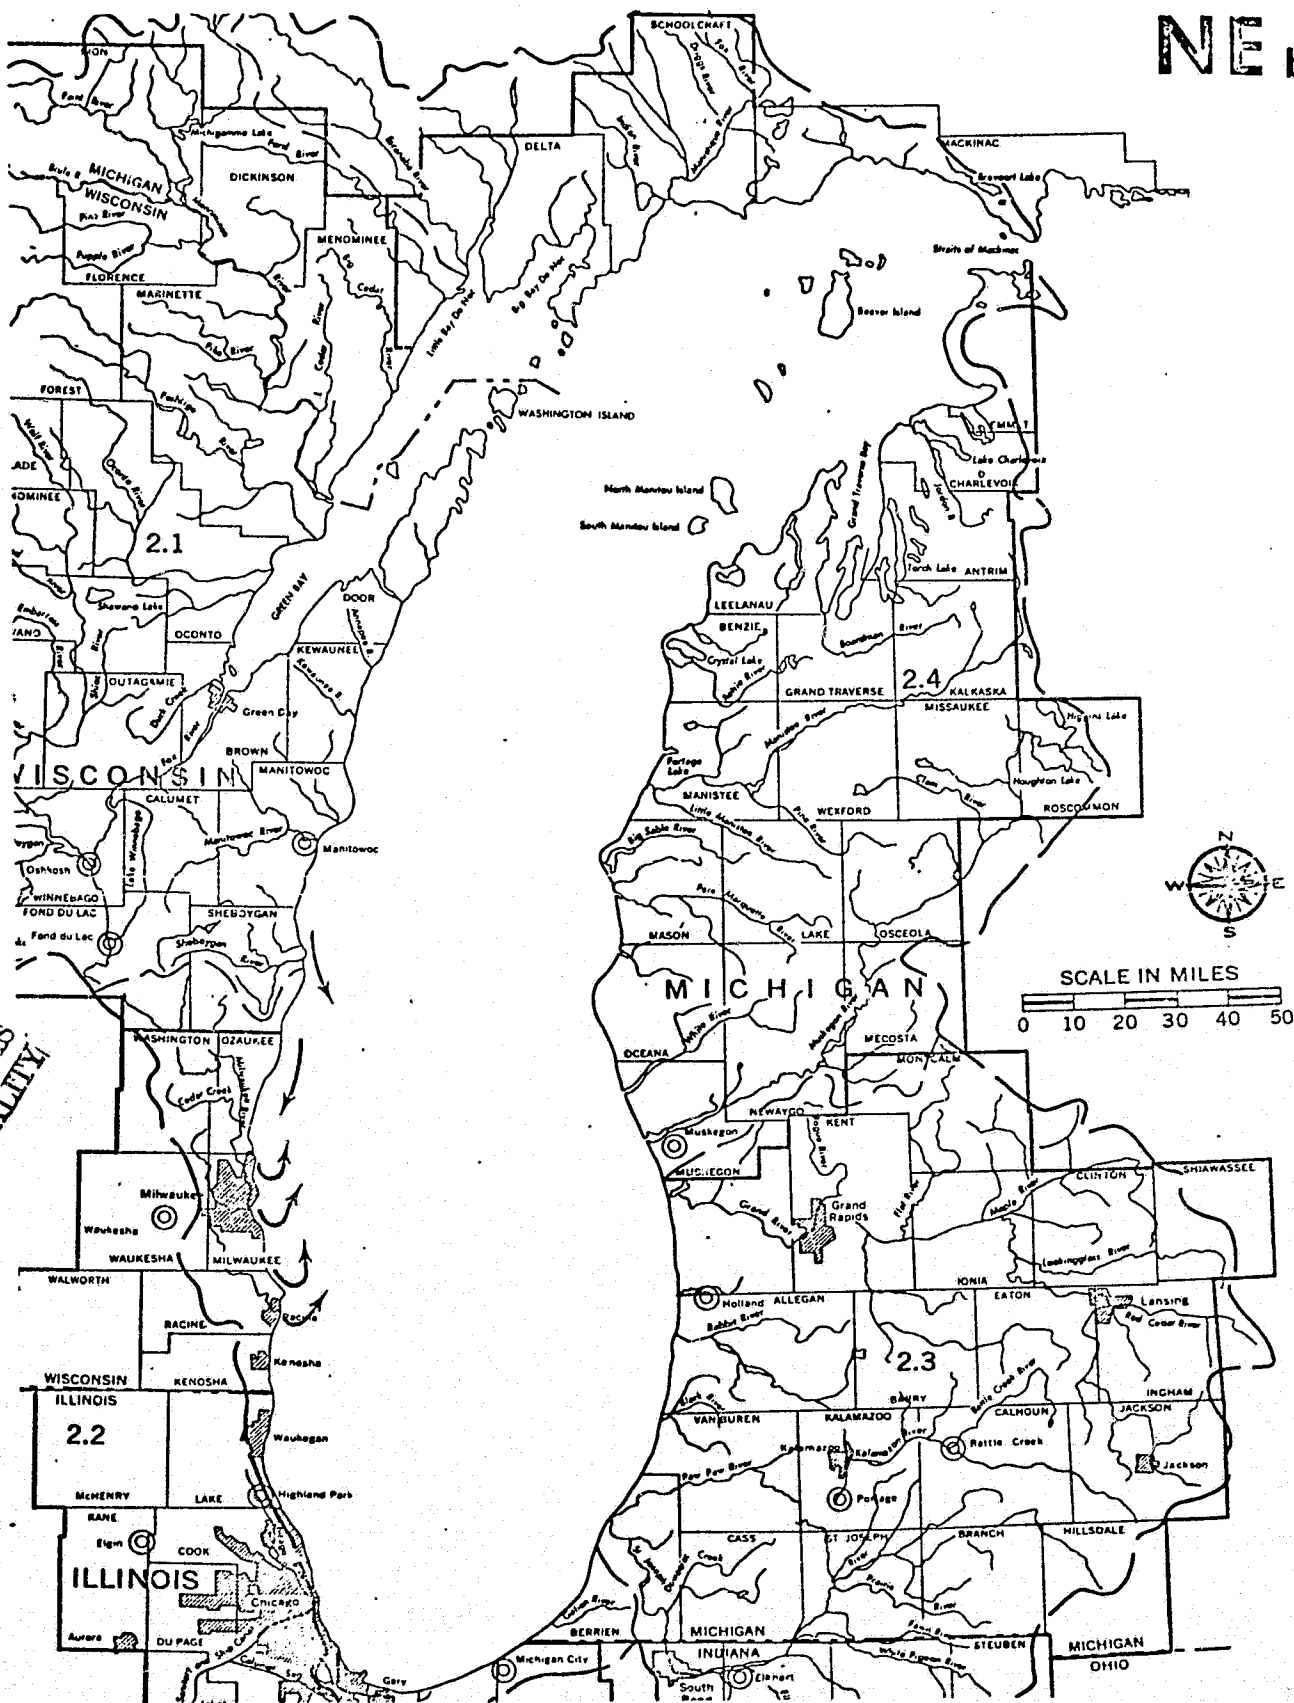

Figure 55a-f. Surface current analyses for southern Lake Michigan as determined from turbidity patterns in ERTS-1 scenes. Weighted wind directions from Table A2 are indicated in upper right-hand corners.

the west shore from Chicago to Sheboygan, suggesting that extensive upwelling was occurring. There may be a small clockwise gyre along the west shore at Waukegan, as suggested by Ayers et al. (1958), but the satellite data are inconclusive.

Westerly Winds - Figure 55e

Three cloud-free ERTS-1 passes (24 November 1972, 13 December 1972, and 4 May 1973) were composited to obtain the current diagram. The clockwise eddy along the east shore discussed above and previously (Ayers et al., 1958 and Bellaire, 1964) apparently has enlarged considerably from its size under other wind regimes. It now extends from Benton Harbor north to Muskegon with a rather elongated shape. Between Gary and Michigan City lies a large counterclockwise gyre, which was discussed under Northerly Winds. In this case, however, the gyre has been displaced to the southeast as compared with other observations. Sediment distribution patterns suggest also the presence of a counterclockwise eddy above the mid-lake sill between Milwaukee and Muskegon; apparently a northwestward-flowing branch of the east shore southward current provides the driving force for this gyre. This was discussed under Northerly Winds. Alongshore currents converge in the Milwaukee - Racine area and then flow offshore, creating upwelling there and contributing to the circulation of the mid-lake eddy. A similar current convergence exists immediately north of Chicago in the Highland Park area; this offshore flow joins the east shore eddy system in the middle of the southern basin.

Northwesterly Winds - Figure 55f

The diagram for northwesterly wind-generated currents is based solely on one ERTS-1 pass (3 August 1973), which coincided with an extensive episode of calcium carbonate precipitation that turned the entire southern basin "milky" in MSS-4 (see Chapter 3). The east shore southward current is very

narrow alongshore. Lakeward of that current is a long narrow band of upwelling from Benton Harbor to Muskegon; this was evident from the sunglint pattern on all four MSS bands (Strong, 1973). In the center of the lake is an elongate clockwise eddy that was discussed above and by Ayers et al. (1958) and Bellaire (1964); this wind regime has apparently displaced this gyre from the east shore toward the lake center. It extends from as far north as Milwaukee south to Benton Harbor. Between Milwaukee and Muskegon lies the mid-lake counterclockwise gyre discussed above; again it is driven by a westward branch of the east shore southward current that forms the northern boundary of the eddy. As discussed above, there is a flattened counterclockwise gyre from Gary to Benton Harbor driven by a branch current of the large central eddy and by the east shore southward current. Sediment patterns indicate a southward-flowing alongshore current at Chicago and suggest that a counterclockwise eddy exists there (Ayers et al., 1958 and Bellaire, 1964). Alongshore currents from Sheboygan to Highland Park are narrow and southward; at Racine and Highland Park they turn offshore (eastward), indicating upwelling at these locations.

Summary

The prevailing wind direction on Lake Michigan is southwesterly, although during winter northwesterly stresses are common. Along the western shore the current favors a northward direction, beginning with northeasterly to easterly winds, and probably (no ERTS-1 observations for easterly, southeasterly or southerly winds along this shore) continuing through southwesterly winds. Along the eastern shore a southward current appears dominant for all winds observed. South of Benton Harbor this flow reverses under southwesterly, westerly and northwesterly winds. The nearshore area between Michigan City, Indiana and Waukegan, Illinois contains an extremely complex circulation. Gyres in the central lake basin have been witnessed under southwesterly,

* - Solar elevation $\geq 55^\circ$ (see Chapter 5).

westerly, northwesterly and northerly resultant wind regimes. Comparison with previously-observed, specific, localized circulations shows good agreement.

Southern Lake Huron

The location of the wind station used in preparation of Southern Lake Huron currents is shown in Figure 56. Also identified in the figure are all locations referred to in the text. Table 7 presents a summary of ERTS-1 scenes utilized in addition to resultant wind direction calculations. Table A3 in the Appendix provides further specifics on southern Lake Huron ERTS-1 views.

Northerly Winds - Figure 57a

The current diagram is based on a single ERTS-1 pass on 27 March 1973. The flow-through current flows southward along the west shore of the lower lake directly into the St. Clair River; there is no apparent southeastward component as Ayers (1959) described. Southwest of Kettle Point appears to be a counterclockwise eddy defined by the flow-through current and the projection of Kettle Point. At Kettle Point upwelling occurs as the currents flow offshore. This opposes the circulation described by Ayers (1959) for northerly wind conditions. From Grand Bend to Goderich lies a large near-shore counterclockwise gyre that apparently exists as a semipermanent feature regardless of wind regime (Ayers et al., 1956). A small weak counterclockwise eddy exists just off MacPherson Point; a similar circulation was described by Ayers et al. (1956) and Ayers (1959) for northerly winds. The current that extends northward from the large counterclockwise eddy leaves the east shore near Clark Point and the winds transport the water across the lake to the southwest, perhaps to join the flow-through current. This original northward current may be a remnant of a previous wind regime or may simply be part of the flow-through current complex as discussed by Ayers (1959) for the Synoptic II cruise under winds from the northern quadrants.

Northeasterly Winds - Figure 57b

ERTS-1 passes on 26 March 1973 and 18 August 1973 were composited for this

analysis. The major features are identical to those that were observed under northerly wind regimes. The general circulation is counterclockwise throughout the southern part of the lake. The flow-through current flows directly to the St. Clair River along the west shore. Southwest of Kettle Point is a nearshore counterclockwise eddy which is apparently created in part by the topographic barrier of Kettle Point. Again between Grand Bend and Goderich along the east shore is a large counterclockwise eddy. The winds transport the mid-lake water to the south and southwest, augmenting the flow-through current. At Lakeport on the west shore a branch current flows abruptly offshore to the northeast, which is inconsistent with all other current indicators.

Easterly Winds - Figure 57c

For easterly wind regimes, only one partly cloudy ERTS-1 pass (20 November 1972) was available for analysis. The only currents that could be determined flowed directly offshore from Goderich to Grand Bend along the east shore, indicating that a band of upwelling existed alongshore.

Southeasterly Winds - Figure 57d

The current diagram was derived from one ERTS-1 pass on 28 September 1972. As discussed above under northerly wind regimes, the general circulation in the southern part of the lake is counterclockwise across the lake and southward into the St. Clair River. At the head of the St. Clair River is a small counterclockwise gyre that was established under northerly winds but not found by Ayers et al. (1956) under any conditions. A larger counterclockwise eddy is located along the curved shoreline between Kettle Point and Grand Bend. The position is somewhat closer to shore than the eddy shown by Ayers et al. (1956) for southerly winds. Along the east shore from Grand Bend to Clark Point upwelling occurs as the currents flow offshore to the northwest. The sediment patterns are inconclusive, but it appears that there is a large counterclockwise gyre in the middle of the area; the southeasterly winds have

displaced this eddy westward from the more nearshore location shown by Ayers et al. (1956) for a wind regime more southerly than normal. Off MacPherson Point a long sediment plume appears to have a counterclockwise component in the same area as under northerly winds; otherwise, the along-shore currents north of Clark Point flow southwesterly to join the overall counterclockwise circulation.

Southerly Winds - Figure 57e

Two relatively cloud-free ERTS-1 passes (19 May 1973 and 7 June 1973) were available to derive the current analysis in Figure 57e. Off the Lakeport-Lexington area is a small clockwise eddy first described by Ayers et al. (1956). From Lexington to Harbor Beach, northeast currents flow offshore creating upwelling and displacing the flow-through current, which is normally alongshore, toward the center of the Lake as described by Ayers et al. (1956). Counterclockwise gyres exist, as discussed above, between Kettle Point and the St. Clair River, northeast of Kettle Point, and southwest of Clark Point. The western portions of each of these individual circulations are incorporated into the southward-flowing mid-lake flow-through current as depicted in the diagram of the selected cruise results (Ayers et al., 1956 and Ayers, 1959). The flow-through current does not appear as a distinct current at the head of the St. Clair River; however, since this flow would draw from relatively clean comparatively sediment-free upwelled water it should be in this area.

Southwesterly Winds

No resultant wind stress was observed from this direction during the period of investigation.

Westerly Winds - Figure 57f

ERTS-1 passed over this area on 14 April 1973 when a westerly wind regime existed. The flow-through current lies along the west shore

where it flows southward, then southeastward and finally southwestward to the St. Clair River. A small clockwise eddy, which is apparently driven by the flow-through current, lies off Lakeport. This was also found by Ayers et al. (1956). A very large elongated counterclockwise gyre exists between Kettle Point and Clark Point, but it is somewhat larger and farther offshore than indicated by Ayers et al. (1956) and Ayers. (1959). The current flowing southwestward from Clark Point appears to help drive this large gyre. There is also a large but weak counterclockwise circulation off MacPherson Point.

Northwesterly Winds - Figure 57g

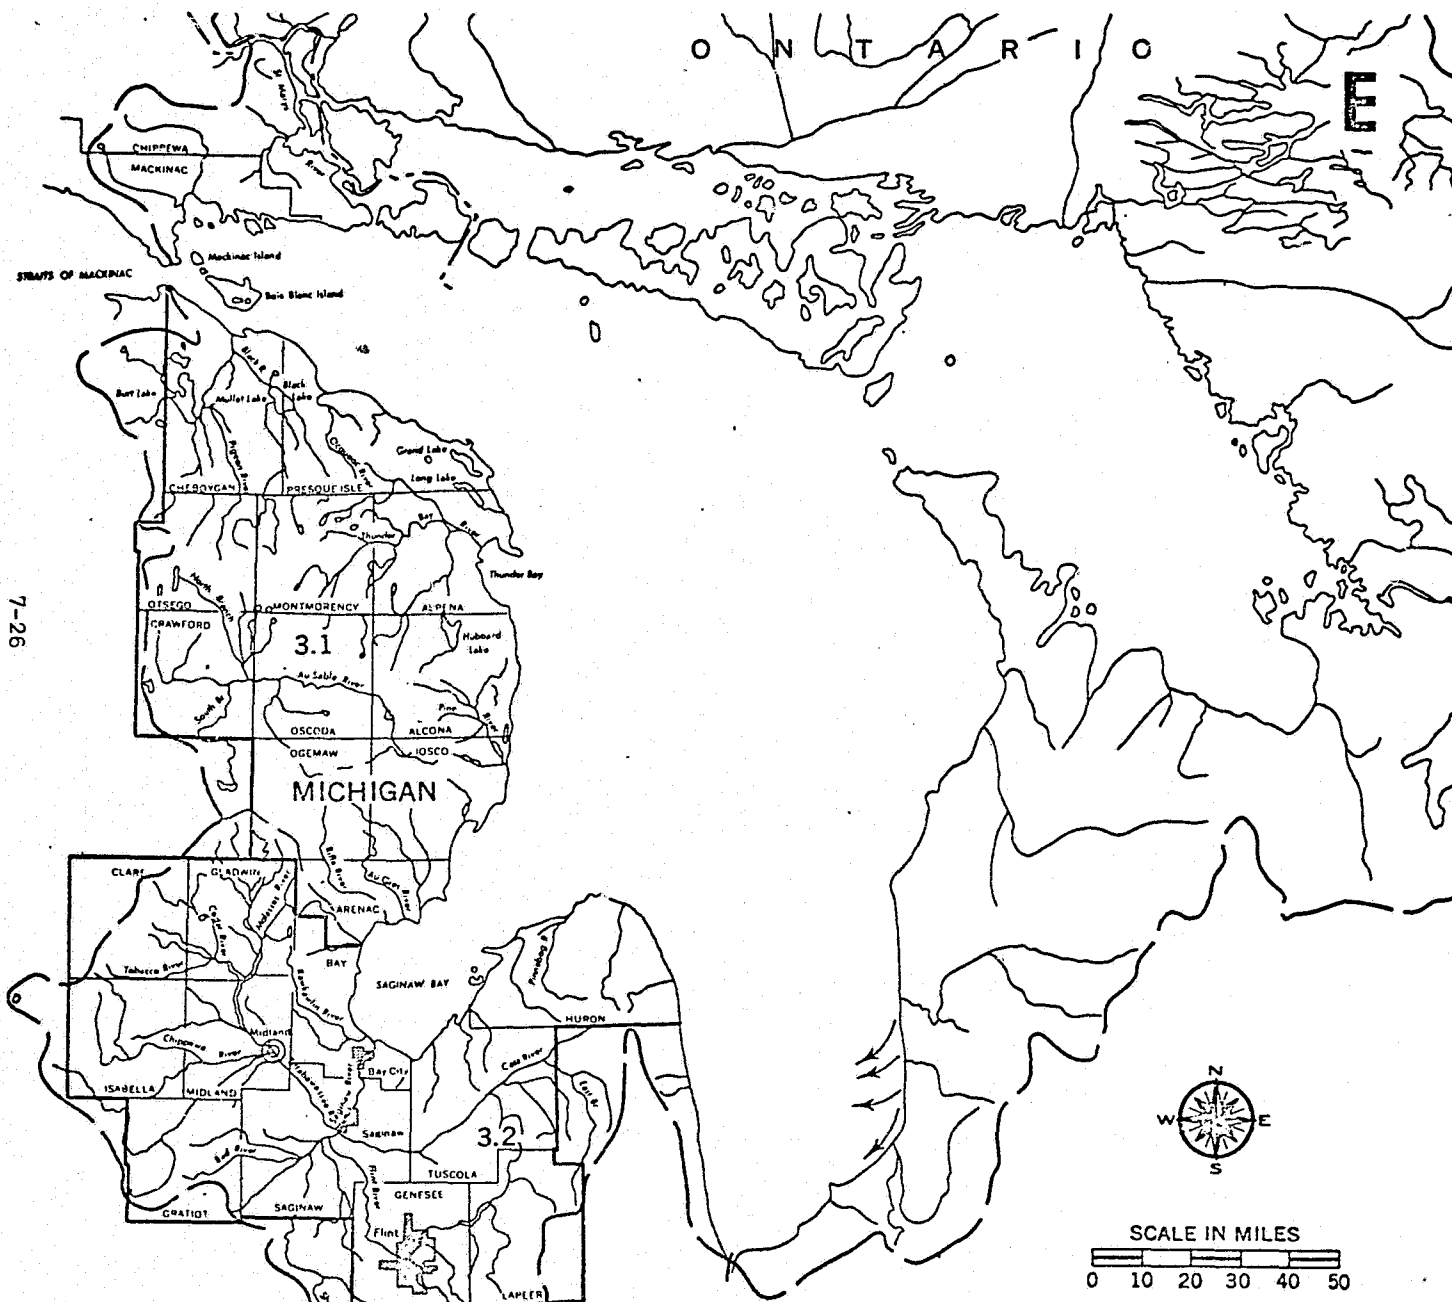

The ERTS-1 pass for 13 April 1973 was used to derive the current diagram in Figure 57g. The flow-through current flows southward along the west shore. At Lexington, it flows southeastward and forms a small clockwise eddy off Lakeport as it returns to the southwest corner of the Lake. This is the "typical" pattern described by Ayers et al. (1956). The sediment patterns in the eastern part of the lake do not define with any certainty the presence of a large counterclockwise gyre, but a counterclockwise circulation is suggested northwest of Clark Point in the middle of the Lake. The situation is very similar to 14 April 1973 (westerly winds), and a gyre was indicated at that time. Off MacPherson Point there exists again a large but weak counterclockwise circulation, augmented by alongshore currents flowing northeast from Clark Point, as Ayers et al. (1956) indicated.

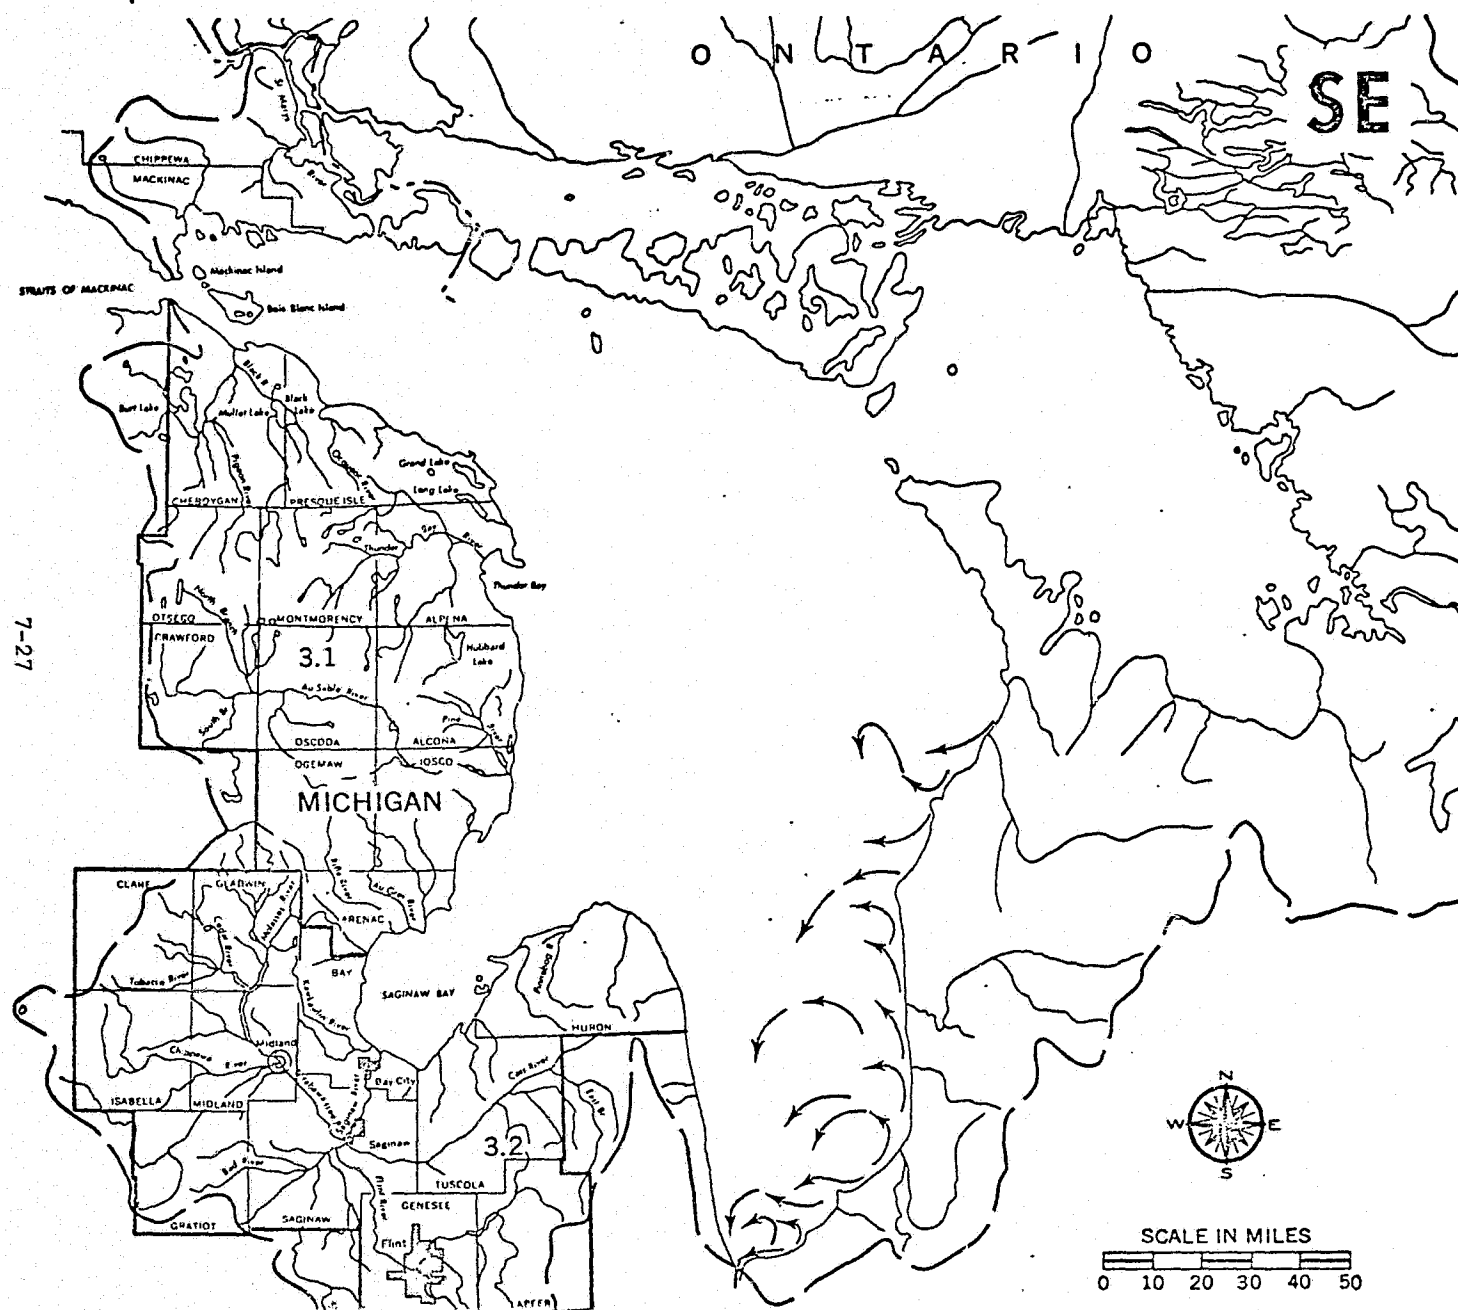

Summary

ERTS-1 observations indicate that the southward-flowing current along the Michigan shoreline of the "Thumb" is only reversed by southerly (and probably southwesterly) resultant wind stress. Along the Canadian shoreline a northward current was observed north of Kettle Point for all winds

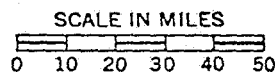

Figure 57a-g. Surface current analyses for southern Lake Huron as determined from turbidity patterns in ERTS-1 scenes. Weighted wind directions from Table A3 are indicated in upper right-hand corners.

SCALE IN MILES

with the exception of easterly--when the flow was offshore. An offshore current component was incorporated in this dominant northward flow whenever wind stress accumulated from the easterly or southerly directions. Also typical for all observed wind directions was a gyre located offshore in the vicinity of Clark Point. Alongshore currents have a tendency to converge in this area. Although the circulation in the central part of the Lake is complex, a decided counterclockwise flow usually prevails.

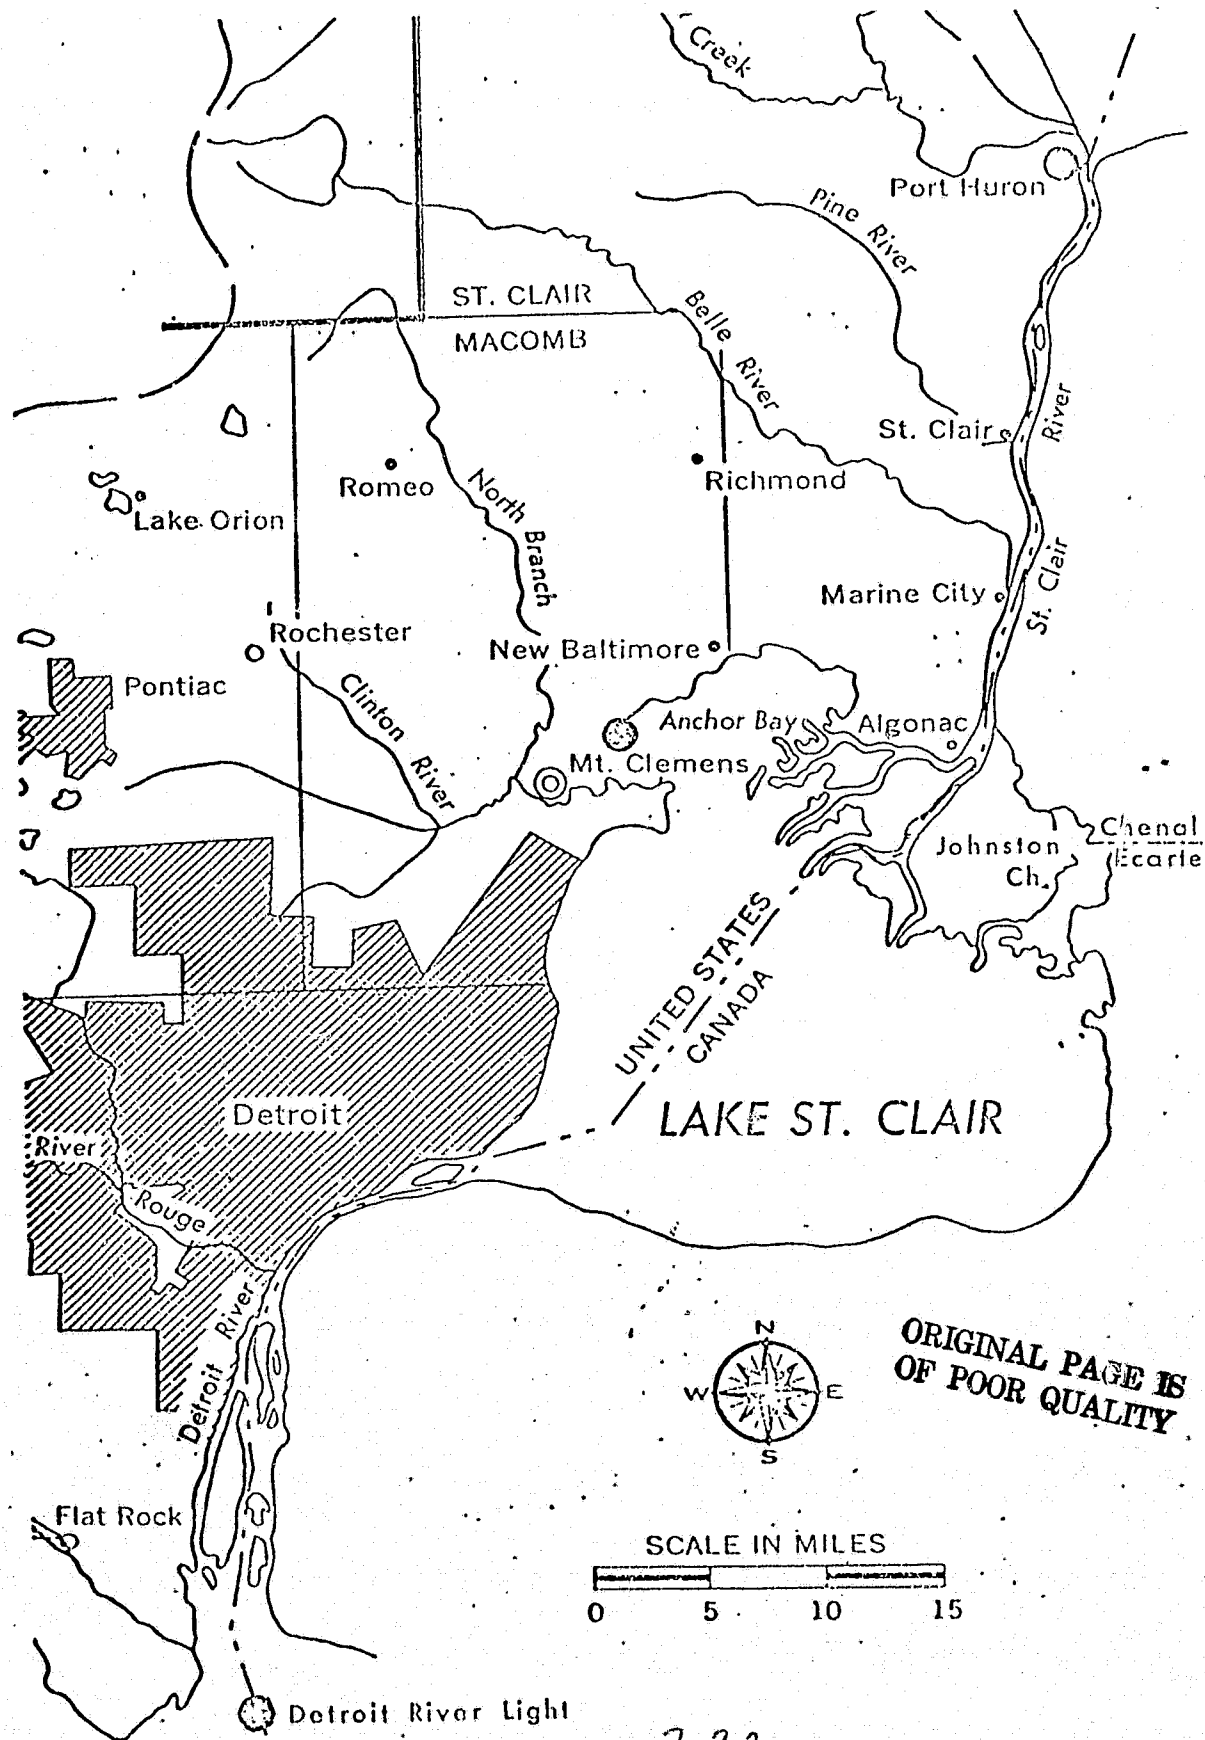

Lake St. Clair

Since there are no regularly maintained meteorological records along Lake St. Clair, three sites are shown in Figure 58. The observations from Selfridge AFB (near Mt. Clemens, Michigan), when available, were accepted as primary input to the resultant wind determinations. Table 8 presents the key ERTS-1 scenes employed for the Lake St. Clair analyses. More complete coverage information is available in Appendix Table A4.

Northerly Winds - Figure 59a

The ERTS-1 pass for 14 April 1973 indicated that, as usual, the water in Lake St. Clair is very turbid, although less so in the surface layers. The currents in Anchor Bay flow westward and southwestward to the outflow of the Clinton River, where the combined currents flow southward along the Detroit shore. A model study by Ayers (1964) has shown Anchor Bay to have an independent clockwise circulation. This view is not supported by this investigation, which indicates that the surface currents in Anchor Bay respond more fully to the wind regime. North of Detroit a branch current flows eastward to the center of the lake. The major component of outflow to the head of the Detroit River appears to come from Chenal Ecarte and Johnston Channels, similar to the situation described by Ayers (1964). Part of this source current flows directly across the

lake southwestward to the Detroit River, and part flows southward along the east shore then westward somewhat offshore. Eastward-flowing along-shore currents are well-defined along the south shore for this wind regime. There is an apparently small weak counterclockwise gyre in the eastern part of the lake; this corresponds to the "water left by previous wind", shown by Ayers (1964), although here it is smaller and less well-defined.

Northeasterly Winds - Figure 59b

The ERTS-1 pass on 27 March 1973 indicated a strong outflow to the head of the Detroit River over the entire lake in response to a northeasterly wind regime. The large counterclockwise gyre that Ayers (1964) found for the southeast portion of the lake was not observed under these conditions. The surface currents in this portion respond to the wind and flow southward from Chenail Ecarte and Johnston Channels, then westward to the Detroit River. Again, there is no evidence to support Ayers' (1964) contention that an independent clockwise gyre exists in Anchor Bay; the sediment patterns strongly indicate that the currents in Anchor Bay flow southward alongshore.

Easterly Winds - Figure 59c

The current diagram shown in Figure 59c was based on the 20 May 1973 ERTS-1 pass; the eastern portion of the lake was partially obscured by clouds. Again, there is no evidence to suggest that the southeastern half of the lake is the site of a large counterclockwise gyre or that Anchor Bay has a clockwise circulation independent of the wind regime (Ayers, 1964). The sediment patterns strongly indicate that there is a rather distinct and straightforward flow-through from the mouth of the St. Clair River to the head of the Detroit River.

Southeasterly Winds Southerly Winds

These conditions were not observed by ERTS-1 during the study period.

Southwesterly Winds - Figure 59d

The surface current analysis in Figure 59d is based on a single ERTS-1 pass on 8 March 1973. The northwest portion of the lake, from the south channel of the St. Clair River to Detroit, was ice-covered and analysis could not be made. The plumes from the St. Clair River and Chenal Ecarte and Johnston Channel are extremely turbid, and remain near the channel mouths because their outflow is directly opposed by the southwesterly stress. There is also a large, vaguely-defined, apparently weak, clockwise circulation in the east part of the lake that developed in response to the wind; this is contradictory to Ayers' (1964) model for this case. The alongshore currents flow eastward along the south shore and partly contribute to the clockwise circulation. The general southwestward outflow current is located only in the central portion of the lake; and under these wind and ice condition, it is relatively narrow. The major source for this current is the outflow from Chenal Ecarte and Johnston Channel. Ayers (1964) indicated another clockwise gyre northwest of the cross-lake outflow current, and a counterclockwise circulation in Anchor Bay; neither of these could be confirmed because of ice cover.

Westerly Winds - Figure 59e

The ERTS-1 pass for 25 June 1973 was employed to derive the surface current diagram. A full counterclockwise gyre was evident in Anchor Bay, as Ayers (1964) indicated. The northwest half of the lake is characterized by southward currents originating from the upper channels of the St. Clair River that turn southwestward somewhat offshore from Detroit. There does not appear to be a significant clockwise circulation north of Detroit as indicated by Ayers (1964). The outflow from the Southeast Bend Cutoff and Chenal Ecarte and Johnston Channel responds to the wind and flows south-eastward and along the east shore, driving a weak clockwise gyre. This

circulation is somewhat larger than the one described in Ayers' (1964) model for this wind condition. West of this clockwise gyre lies a smaller weak counterclockwise eddy that may be driven by the outflow current and a branch from the clockwise gyre. Alongshore currents flow eastward along the south shore, separated from both eddies by a vague westward-flowing outflow.

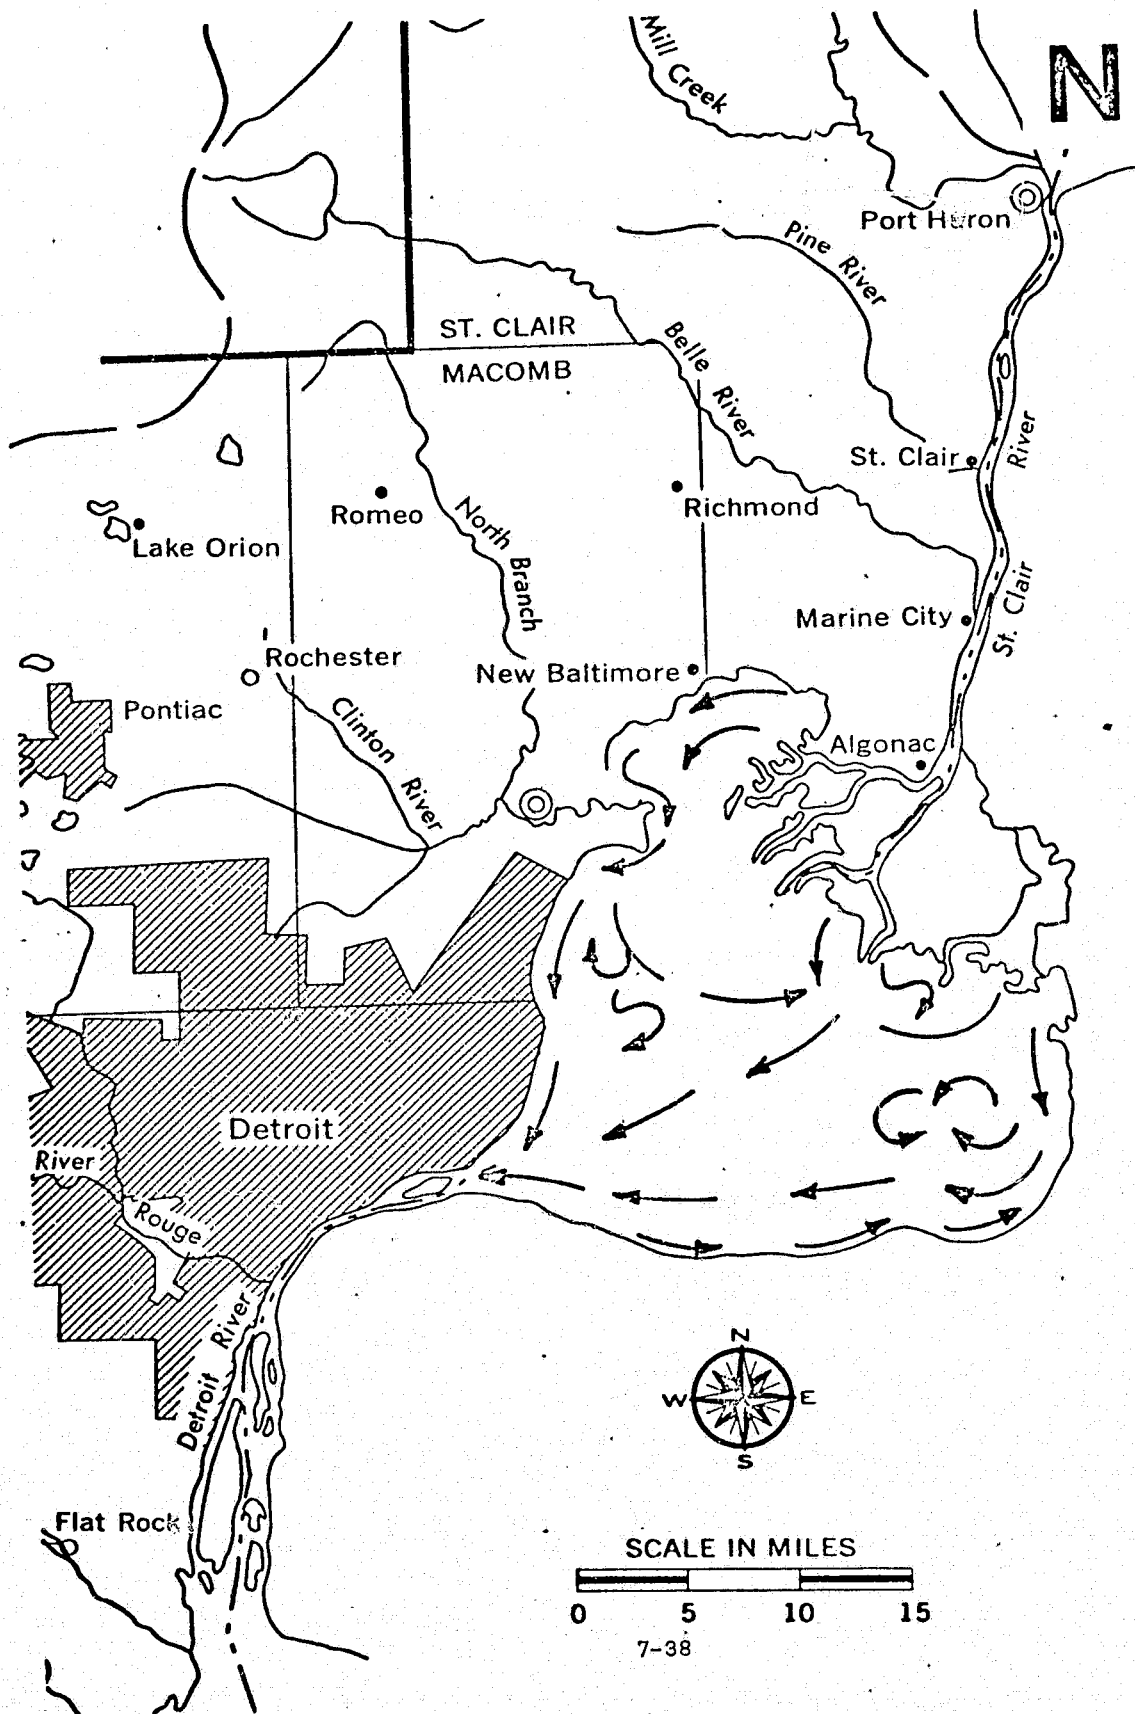

Northwesterly Winds - Figure 59f

The surface current analysis for northwesterly resultant winds was derived from a single ERTS-1 overpass on 13 April 1973. Here there was very little agreement with Ayers' (1964) model for a northwesterly wind regime. The outflow from the upper channels of the St. Clair River flows southward and southwestward directly to the Detroit River. The outflow from Chenal Ecarte and Johnston Channel is first transported southeastward then southwestward across the lake to join the general outflow, in the process driving a small counterclockwise gyre in the east portion of the lake. This eddy apparently is much less significant than Ayers (1964) believed. The cross-lake current flows southwestward, not southeastward as Ayers (1964) illustrated. Alongshore currents flow eastward along the south shore.

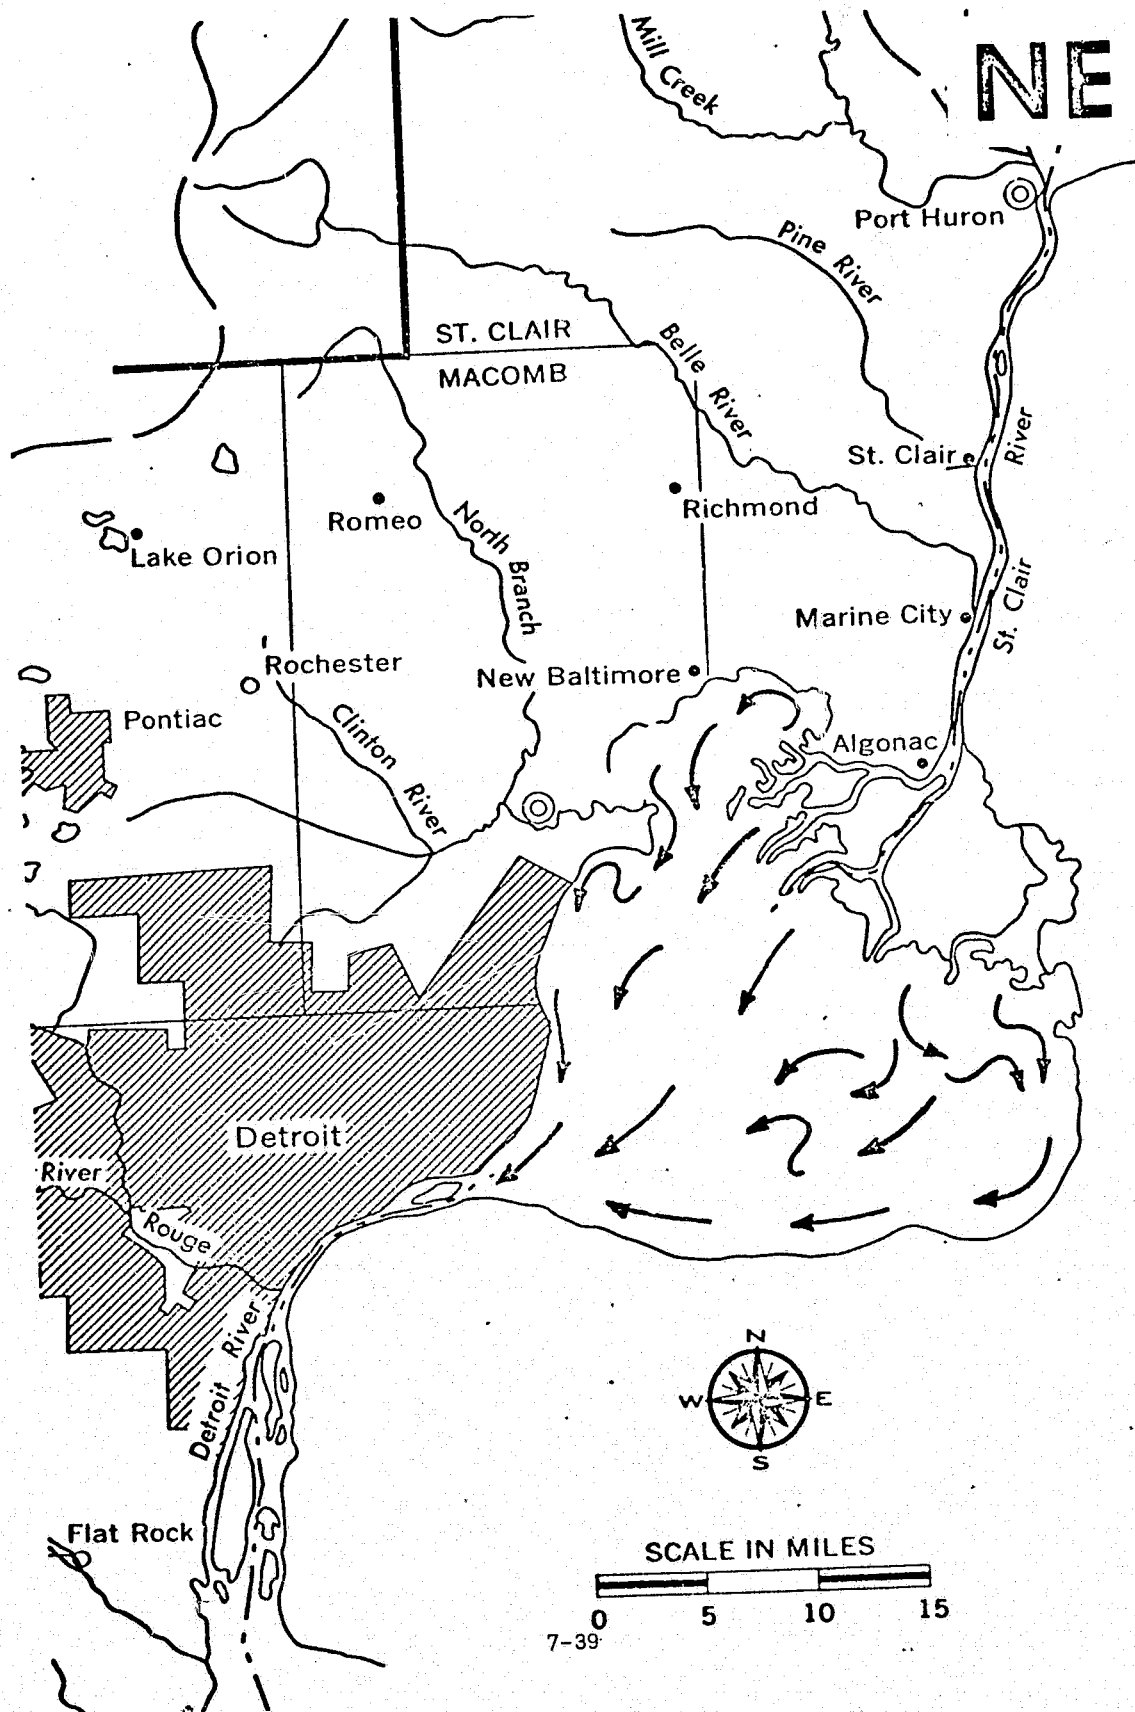

Summary

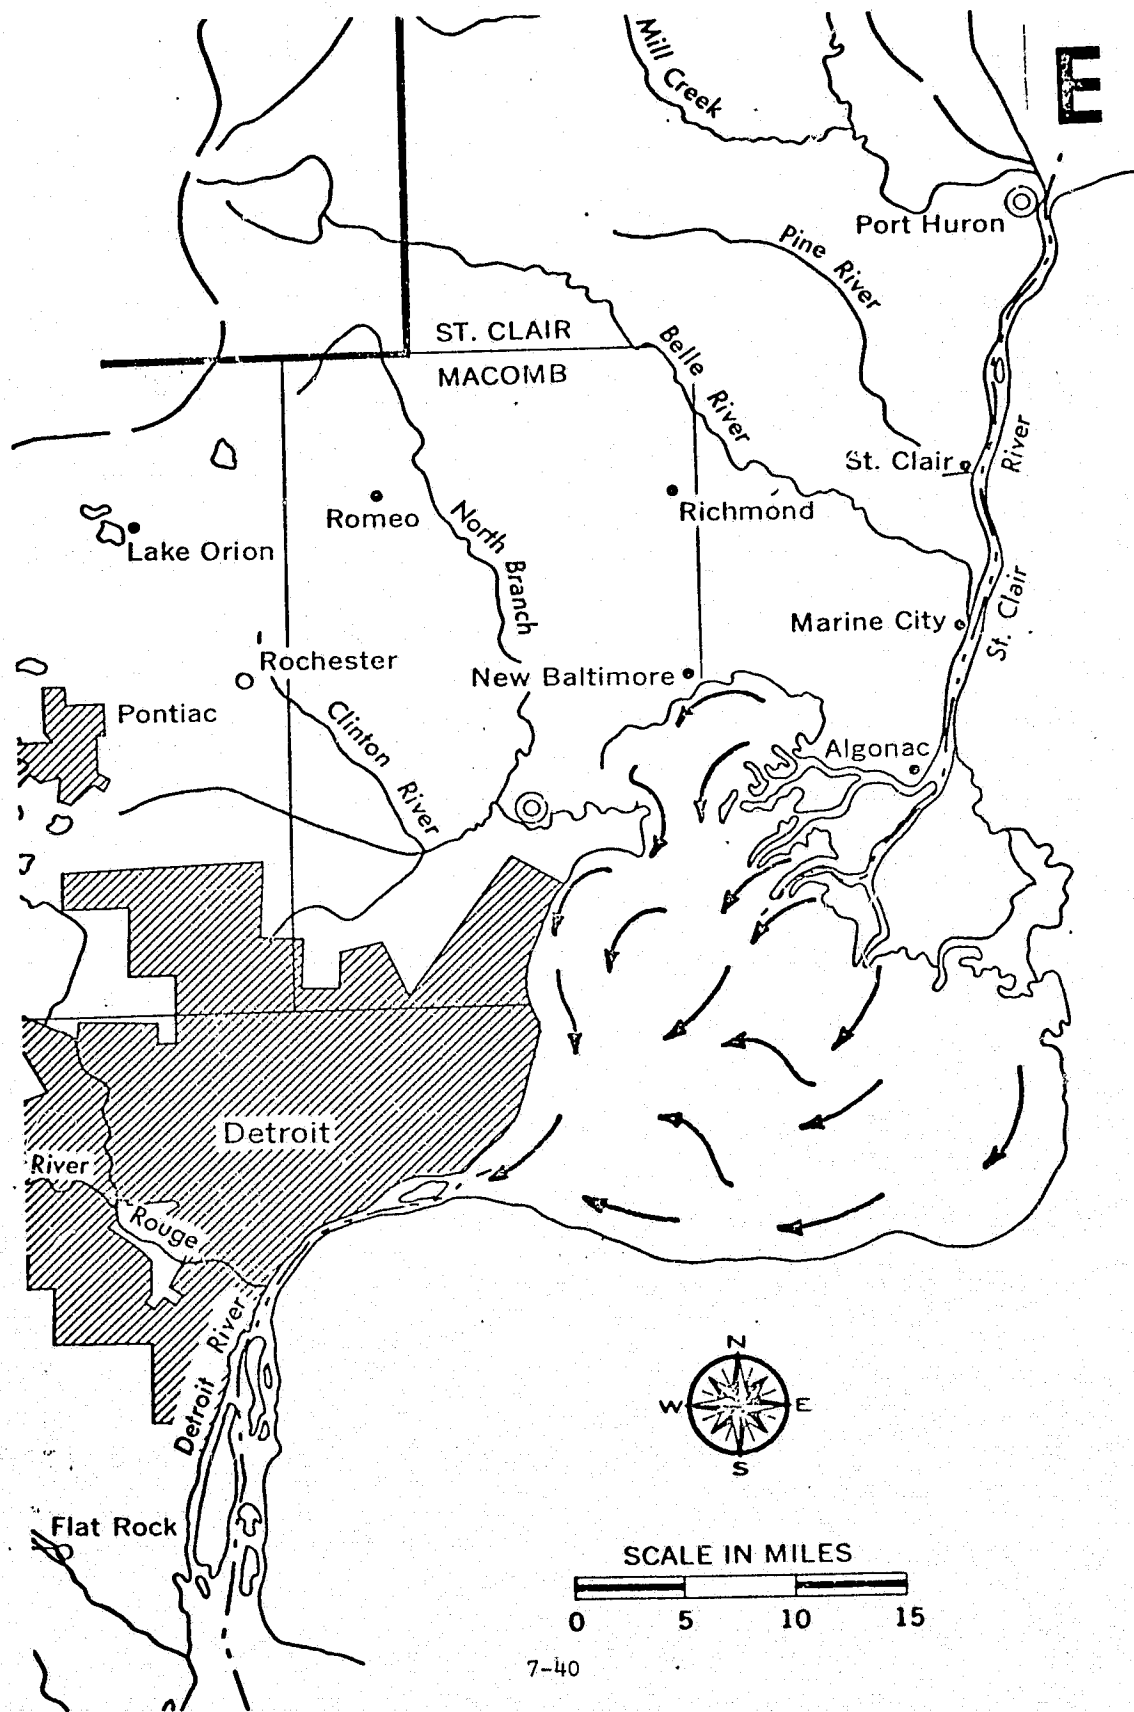

The ERTS-1 observations reveal that a preferred southward-flowing current is found along the Detroit shoreline. It is presumed, as indicated by the Ayers (1964) model, that only a southwesterly resultant wind stress reverses this southward flow. No ERTS-1 data were available for charting this condition along the Detroit shoreline because of ice cover at the time of the only sufficiently cloud-free overpass to coincide with a southwesterly wind regime. Currents along the southern shoreline (Canada) flow

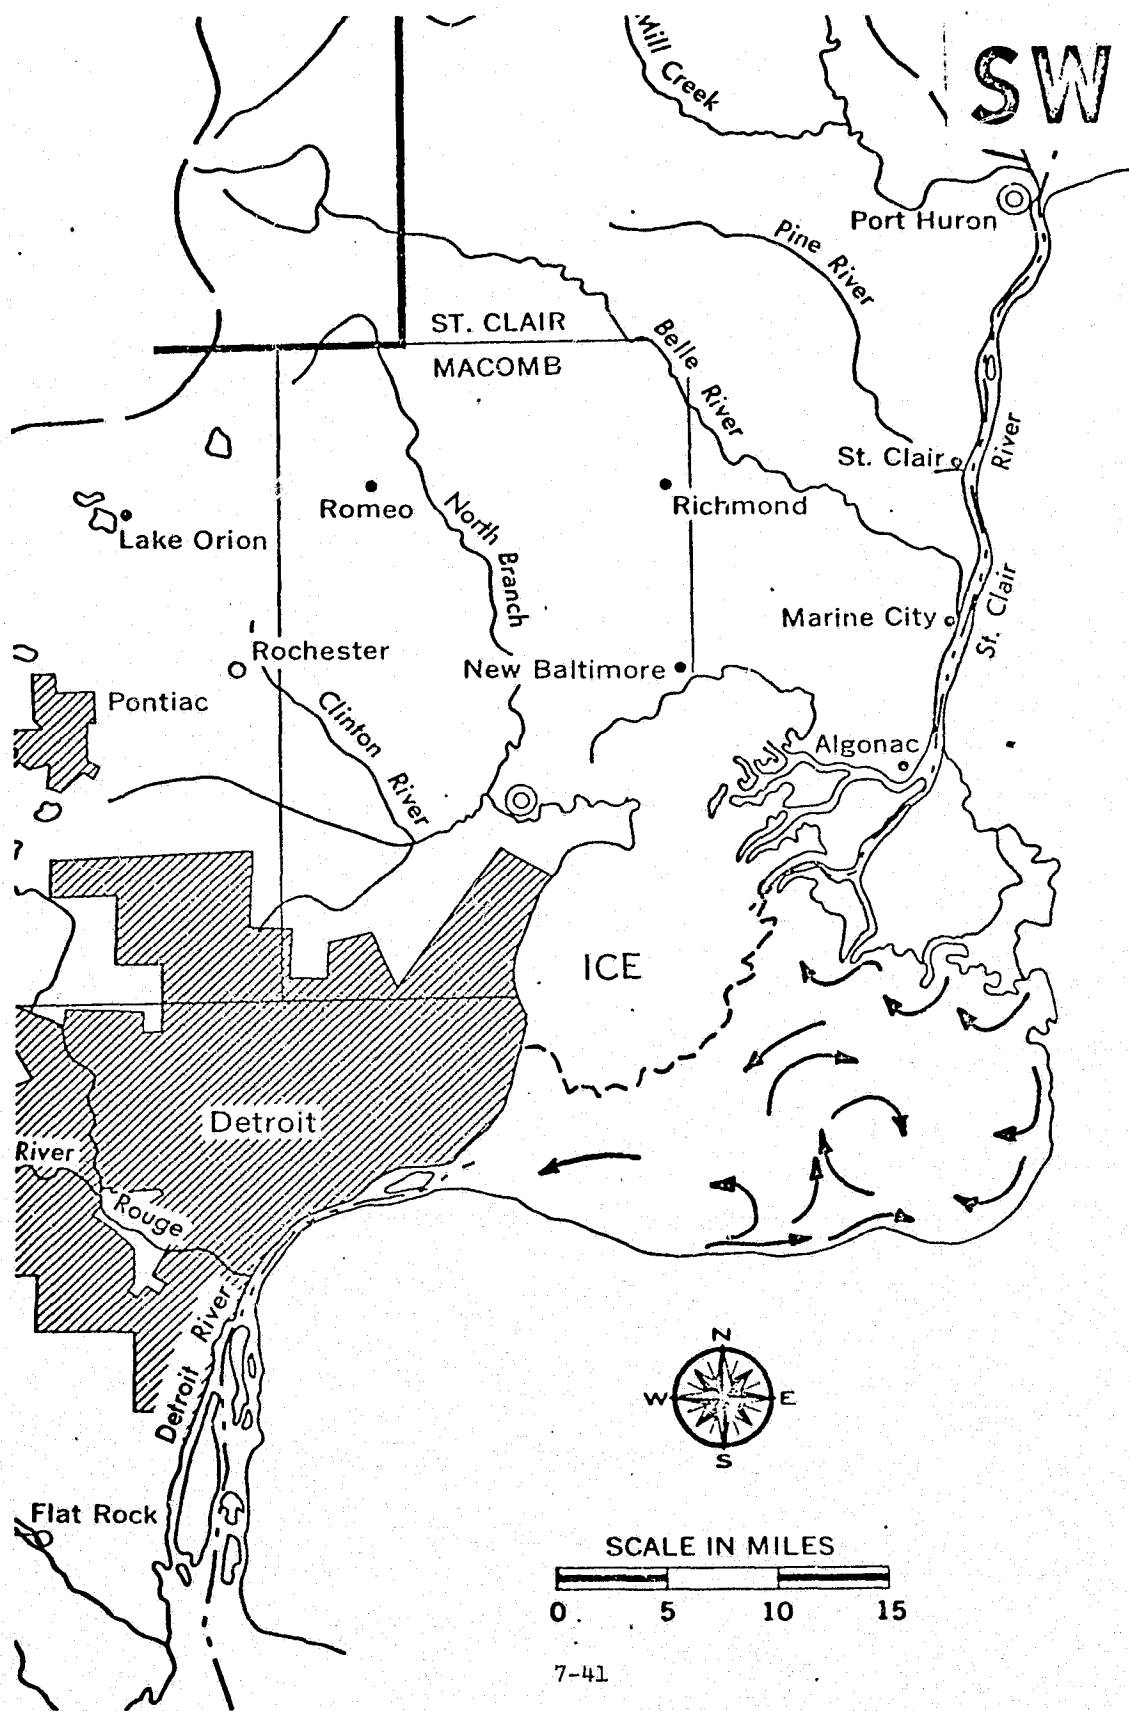

Figure 59a-f. Surface current analyses for Lake St. Clair as determined from turbidity patterns in ERTS-1 scenes. Weighted wind directions from Table A4 are indicated in upper right-hand corners.

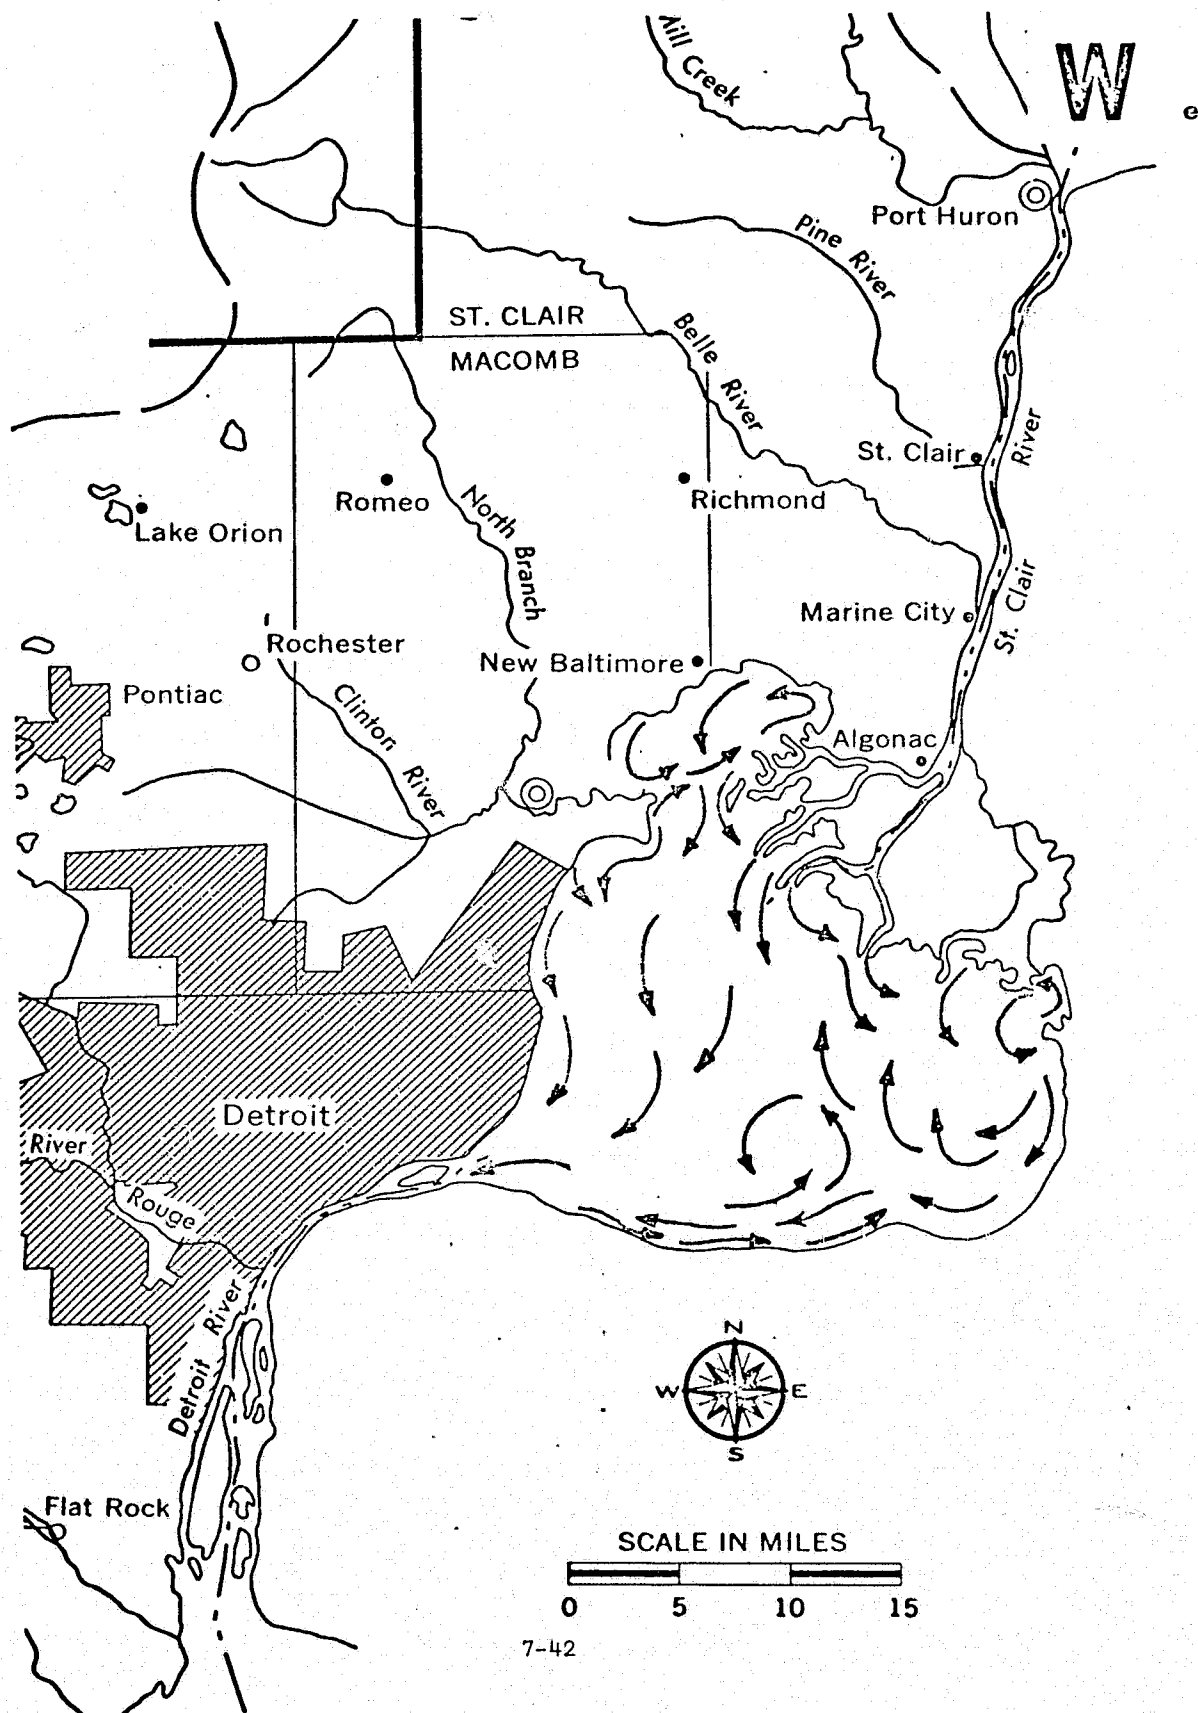

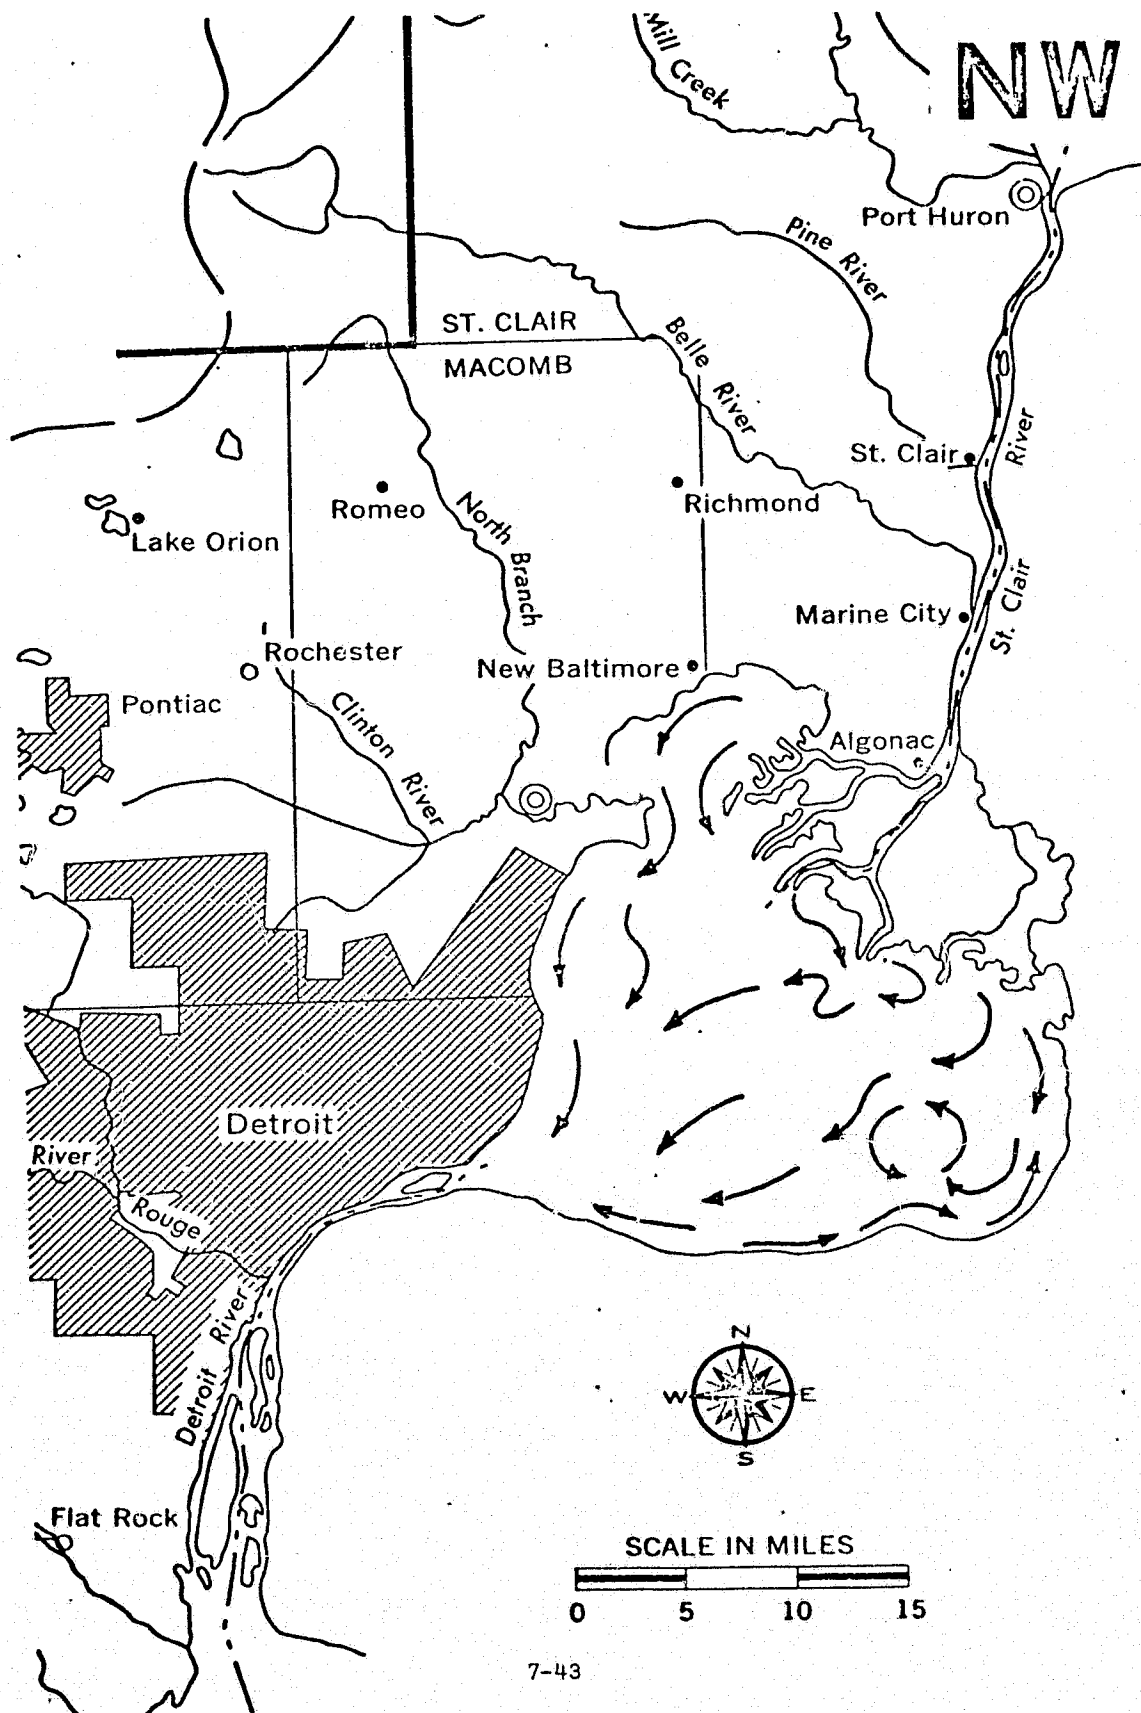

7-38

eastward away from the headwaters of the Detroit River for all wind conditions observed except northeasterly and easterly. At times, however, this eastward flow is opposed offshore by westward flow.

Mid-lake circulations are complex under most winds, with several gyres present. Easterly wind stress produces the most straightforward circulation--the one most expected for a shallow flow-through lake. The prevailing wind (westerly) shows the Canadian portion of the lake benefiting most from the clean, clear waters of the St. Clair River and Lake Huron.

Lake Erie

The location chart for the Lake Erie analyses (Figure 60) shows six stations that were used for resultant wind vectors. These U.S. Coast Guard observations were considered to be representative for the immediate area of Lake Erie surrounding the respective locations. Table 9 provides a listing of all ERTS-1 scenes used in producing the surface current charts. The resulting charts are derived from several ERTS-1 scenes in the form of composite analyses. A more complete listing of all ERTS-1 passes over Lake Erie can be found in Appendix Table A5.

Northerly Winds - Figure 61a

This current diagram was based on two ERTS-1 passes (14 and 29 April 1973) and is obviously incomplete, the major gap being the central basin. Outflow from the Detroit and Maumee rivers flows southeastward and eastward, filling the west basin with highly turbid water. This flow continues eastward beyond Cleveland along the south shore. Local deflection of currents occurs around Pelee Island but a general eastward transport is maintained. There is a small clockwise circulation west of Point Pelee along the north shore; upwelling may be occurring in this area as well as south of Point Pelee where the alongshore currents converge and are no longer influenced

* - Solar elevation $\geq 55^\circ$ (see Chapter 5).

by the boundary geometry. There a series of small counterclockwise circulations is established, perhaps as a result of wind or river outflow pulses. As Harrington (1895) and Hough (1958) showed, there appears to be a large counterclockwise eddy alongshore between Point Pelee and Pte. aux Pins. Although the analysis is incomplete, alongshore currents would appear to converge in the vicinity of Erie, Pennsylvania.

Northeasterly Winds - Figure 61b

Northeasterly winds prevailed during the ERTS-1 overpasses on 20 November 1972, and 26-27 March 1973. Figure 59b indicates a counterclockwise flow of surface currents in Long Point Bay, and apparently two minor clockwise gyres south and west of Long Point along the shore; these may be parts of a larger clockwise gyre in the central basin (Gedney and Lick, 1972). Midway between Long Point and Pte. aux Pins, the alongshore currents change direction and flow southwestward to Point Pelee, indicating that upwelling may be occurring extensively along the north shore. South of Pte. aux Pins there appears to be a small nearshore counterclockwise gyre. At Point Pelee the alongshore currents converge and there is a hint of incipient counterclockwise circulation from the sediment patterns. The outflow from the Detroit River is transported southward into the west basin and eastward alongshore to Point Pelee. The outflow of the Maumee River is directly opposed by the northeasterly wind; the result is a complex convergence of the two river outflows in the west basin. North of Port Clinton, Ohio is a small counterclockwise eddy. A current flows northward between Kelleys Island and Bass Islands. East of Sandusky Bay, the alongshore currents flow eastward. No additional sufficiently cloud-free observations were available for the remainder of the Lake Erie circulation pattern under northeasterly resultant wind.

Easterly Winds - Figure 6lc

The incomplete analysis in Figure 6lc was derived from the only two cloud-free ERTS-1 passes (28 September 1972 and 26 March 1973) that coincided with easterly winds. A large clockwise circulation in the central basin is indicated by the sediment patterns southwest of Long Point; the alongshore currents initially flow eastward, then branch southward and southwestward in response to the wind. A similar extensive gyre was described by Gedney and Lick (1972). The extreme western part of the lake was the only other area adequately covered by ERTS-1 under these conditions. The outflow currents from the Detroit and Maumee Rivers are forced to remain nearshore by the easterly wind. The Detroit River outflow flows directly southward, while the Maumee discharge flows northward to converge with the Detroit River plume and thence southeastward alongshore to Port Clinton.

Southeasterly Winds - Figure 6ld

Southeasterly winds prevailed during the ERTS-1 overpasses on 25 June 1973 and 4 September 1973; the resulting surface current analysis is relatively complete. As mentioned above the large clockwise gyre in the central basin appears to be a semipermanent feature; the alongshore currents flow eastward to Long Point, then turn lakeward (Gedney and Lick, 1972). Near Pte. aux Pins the alongshore currents flow eastward then southward the center of the lake, suggesting upwelling at Pte. aux Pins. At Point Pelee the alongshore currents converge and appear to radiate eastward toward the currents from Pte. aux Pins, southward to the current leaving the west basin, and westward to form a clockwise gyre west of Point Pelee. The outflow from the Detroit River meanders southeastward through the west basin and exits at mid-lake. The Maumee River plume forms a clockwise

gyre northeast of Toledo, but flows mainly eastward to Port Clinton. The Huron River discharge flows northward and eastward, then northwestward to meet the currents coming south from Point Pelee, and then exits from the west basin. Alongshore currents flow in a wide diffuse band, generally eastward along the south shore from Lorain to Buffalo, as Harrington (1895) indicated. There is a northeastward component to this flow due to the prevailing winds; river discharges extend lakeward farther than usual along the south shore.

Southerly Winds - Figure 6le

A full analysis was made of the surface currents for the western half of Lake Erie based on the ERTS-1 overpasses of 8 March 1973, 7 June 1973, and 3 December 1973, under southerly wind regimes. The western basin is marked by a general outflow to the east. The Maumee River outflow initially flows northward, then eastward in a vaguely clockwise circulation. The southerly winds produce a distinct outflow from Sandusky Bay. There is a series of small counterclockwise eddies south of Point Pelee as the eastward and southward alongshore currents leave the restricting influence of lake boundary. Alongshore currents converge at Pte. aux Pins and turn eastward and southward, suggesting that upwelling may be occurring at Pte. aux Pins. There appears to be an elongate counterclockwise gyre along the south shore from Lorain to Ashtabula. Gedney and Lick (1972) substantiate this feature. Within this area, local currents flow directly offshore at Cleveland, indicating that upwelling may be occurring there.

Southwesterly Winds - Figure 6lf

Southwesterly winds prevailed during the ERTS-1 overpass on 24 June 1973. In the west basin, the alongshore current flows eastward to Point Pelee, then southward and westward back into the basin north of Pelee Island. The

winds again force water out of Sandusky Bay alongshore to Lorain. At Cleveland and Ashtabula there appear to be two distinct counterclockwise gyres. These may be part of a larger elongate near-shore circulation as discussed above under Southerly Winds. Alongshore currents converge at Pte. aux Pins, forming a vaguely-defined clockwise circulation south of that promontory. A branch of the current that flows through the west basin from Point Pelee flows eastward as part of the general flow-through current in the Lake Erie basin.

Westerly Winds - Figure 6lg

Only one ERTS-1 pass (18 May 1973) was clear enough for a preliminary analysis of the surface currents under prevailing westerly winds. The only feature of note is a general easterly flow over the entire lake surface in the central basin. North of Ashtabula there is a northeasterly component of transport that may indicate some upwelling alongshore between Ashtabula and Erie. The alongshore current west of Long Point appears very narrow as defined by the sediment distribution patterns.

Northwesterly Winds - Figure 6lh

Northwesterly resultant winds prevailed during the ERTS-1 passes for 9 September 1972, 13 April 1973, and 30 April 1973; the surface current analysis for the west and central basins is given in Figure 6lh. The combined outflow from the Detroit and Maumee Rivers flows southeastward through the west basin. There is a general clockwise circulation around the Bass Islands and west of Sandusky Bay. Alongshore currents converge at Point Pelee, and small counterclockwise eddies are generated; under other wind regimes these eddies were directly south of Point Pelee, but here they have been displaced eastward by the westerly component of the wind. The eastward-flowing alongshore currents that turn lakeward at

Pte. aux Pins may be part of a clockwise gyre there; the sediment patterns are not conclusive in this region. There is a distinct nearshore counterclockwise gyre at Cleveland. This may be the western edge of the above-mentioned larger counterclockwise circulation that lies near the south shore from Cleveland to Erie (Gedney and Lick, 1972). A number of currents flow directly northward along the south shore, suggesting that extensive upwelling was occurring there during the satellite overpasses. Surface currents in mid-lake flow generally eastward. No coverage was available for the eastern basin under this wind condition.

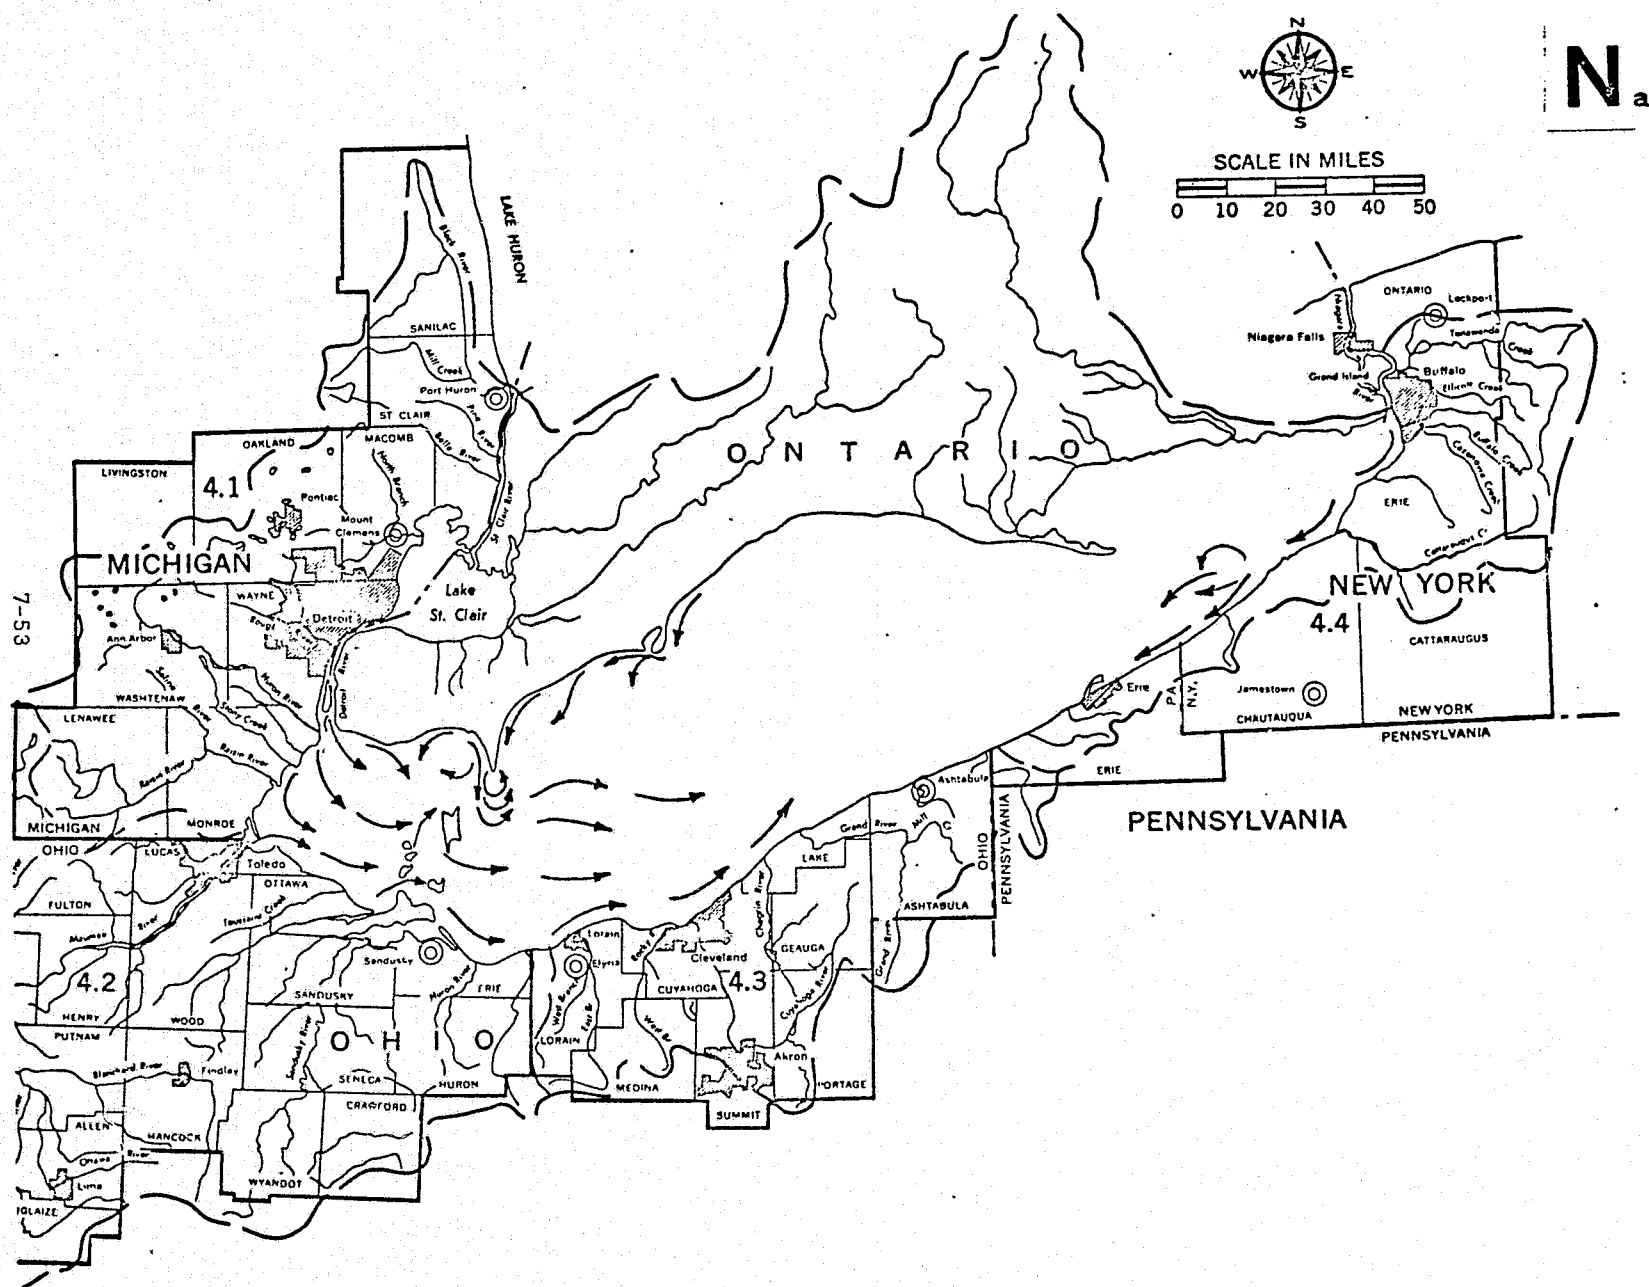

Summary

Eastward flow of surface water from the shallow western basin of Lake Erie into the middle basin is most obvious during northwesterly and northerly (and probably westerly) wind stresses. The reverse wind directions, especially east and southeasterly, appear to hold the effluents from the Detroit and Maumee Rivers in the western basin as would be expected.

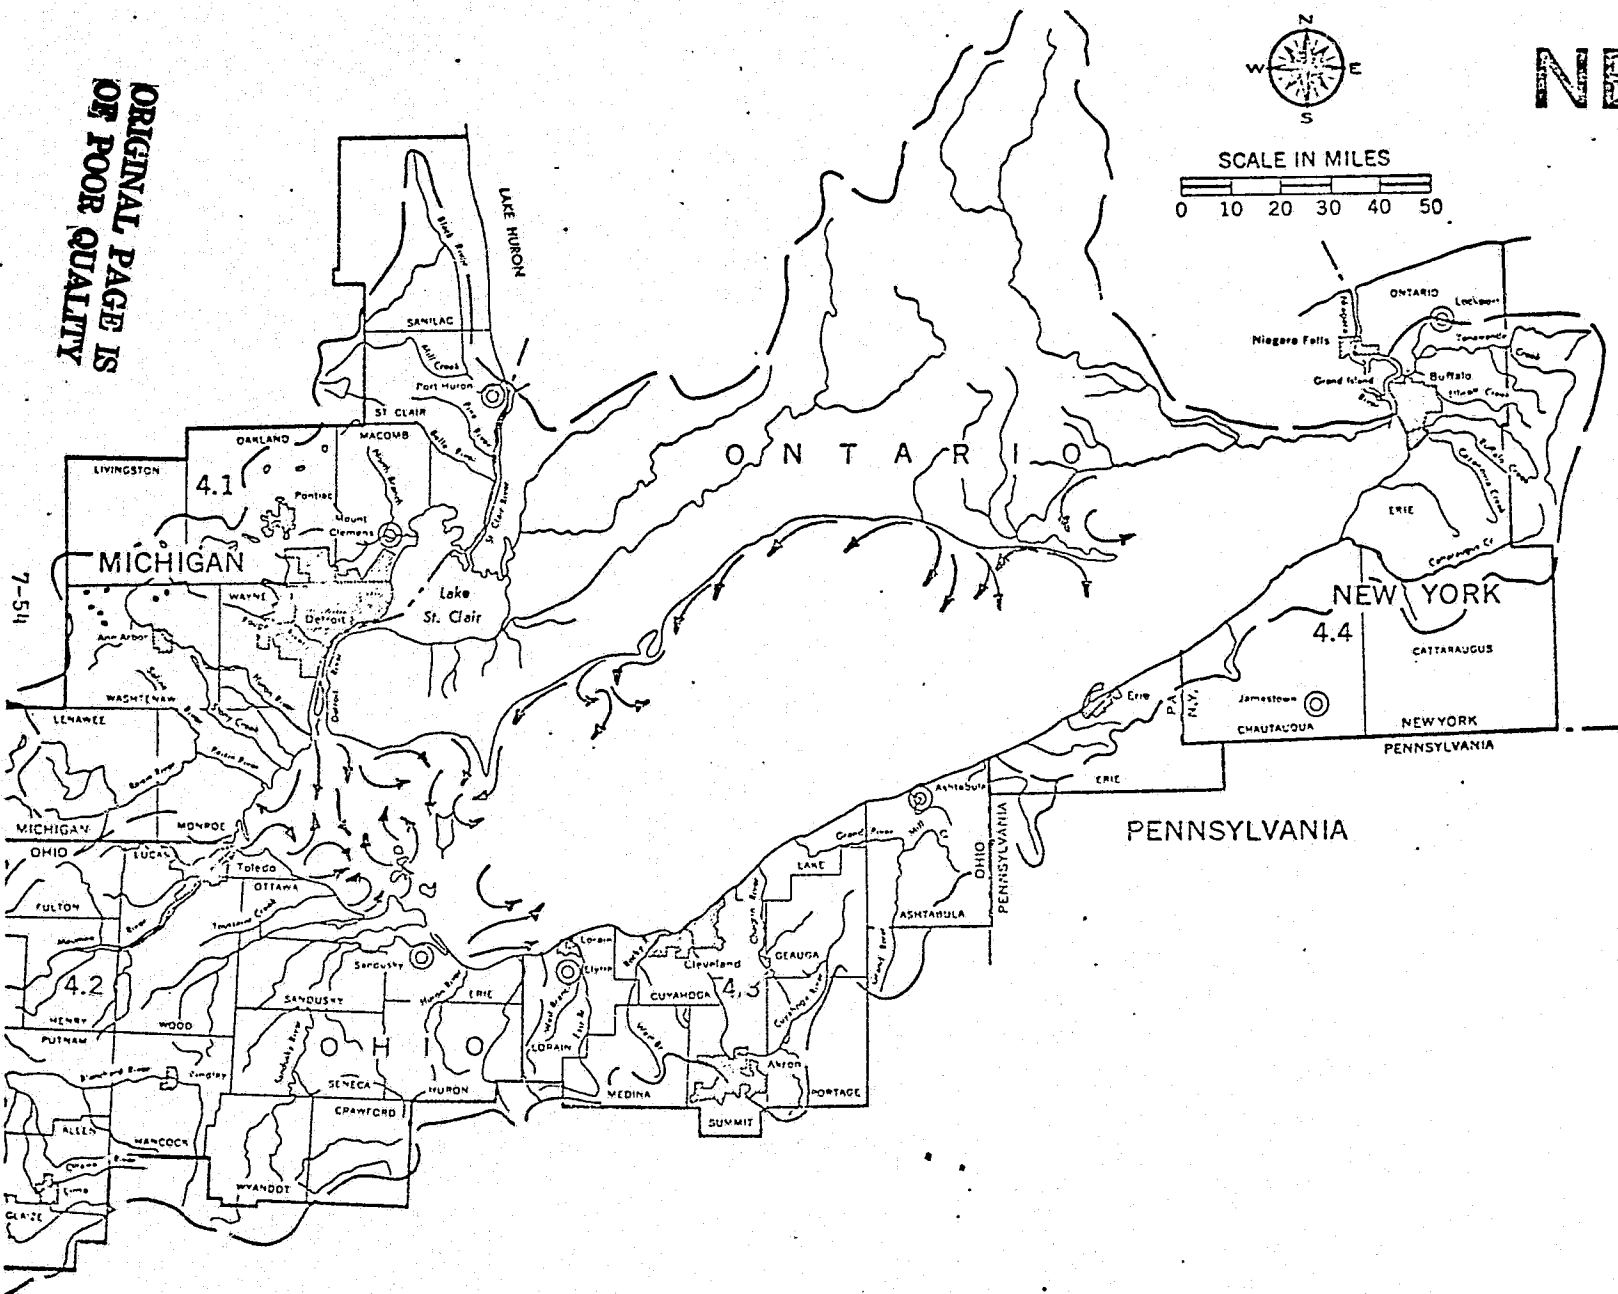

East of Sandusky, Ohio, along the southern (U.S.) shoreline the favored current is eastward. Under southeasterly, southerly, and southwesterly winds, alongshore eddies and return circulations are occasionally noted. Perhaps the most complex condition along the southern shore was noted under northwesterly wind stress; then much of the observed surface current was directed offshore.

Currents show a tendency to form gyres off the three points along the Canadian shore--Point Pelee being a producer of the most dramatic lake boundary effects. A clockwise gyre between Long Point and Pte. aux Pins is well developed under easterly and southeasterly wind stresses. West-to-east flow in the middle basin is best developed during southwesterly and westerly

stresses. Between Erie, Pennsylvania and Ashtabula, Ohio, a brief reverse circulation is occasionally observed.

The only westward currents observed in the eastern basin of Lake Erie occurred under northerly wind stress. It is believed that a similar current should be observed under northeasterly and easterly resultant winds.

Lake Ontario

Figure 62 locates the three wind record sites utilized in the Lake Ontario current charts. Table 10 lists all ERTS-1 scenes utilized in producing the following surface current charts. These charts are composited from several ERTS-1 scenes as it takes three days to cover the entire lake. See the Appendix (Table A6) for a more complete listing of ERTS-1 imagery available during the study period.

Northerly Winds - Figure 63a

The ERTS-1 pass for 29 January 1973, although partially obscured by clouds, was used to derive the current diagram for northerly winds shown in Figure 63a. Upwelling apparently occurred extensively along the north shore as the currents were driven southwesterly in response to the prevailing winds. In the west end of the lake, a counterclockwise gyre began at Toronto, driven by the winds and modified by the lake boundary. This circulation was first described by Harrington (1895) and later substantiated by Simons and Jordon (1972). Its eastern extent is limited by the Niagara River plume which flows offshore and is divided by the wind into eastward- and westward-flowing branches. The sediment pattern is not fully developed, but a small nearshore clockwise eddy may be established by the eastward-flowing branch. The easternmost currents flowing offshore from the Canadian shore turn southward and southeastward at mid-lake suggesting that a large counterclockwise circulation has been established in the

* - Solar elevation $\geq 55^\circ$ (see Chapter 5).

eastern basin, with the currents perhaps turning eastward at the south shore and finally northeastward out through the St. Lawrence River.

Northeasterly Winds - Figure 63b

The surface current analysis shown was derived from the ERTS-1 pass for 24 March 1973 for northeasterly winds. The currents along the Canadian shore have a more westerly component than the alongshore currents for northerly winds, as is to be expected. The counterclockwise eddy off Toronto evidently is much smaller than it was under northerly winds, extending only to mid-lake. The Niagara River plume is forced to the northwest by the winds, as are other visible remnant pulses of the discharge. Apparently at mid-lake there exists an eastward return flow which is fed by both the southwestward and northwestward-flowing currents from opposite shores. The alongshore currents flow eastward between the Niagara River mouth and Rochester, where they are interrupted by the outflow from the Rochester embayment and the Genesee River that perturbs the general eastward flow to the St. Lawrence River. The data in the eastern region are incomplete, but there may exist a large counterclockwise cell in the central and eastern basins as suggested by Simons and Jordon (1972) for winds with an easterly resultant component.

Easterly

No adequate imagery available for analysis.

Southeasterly

No observable sediment features were detected in imagery available under this resultant wind direction.

Southerly Winds - Figure 63c

The ERTS-1 overpasses for 3 September 1973 and 25 October 1973 were used to construct the surface current diagram for southerly winds. The entire western half of the Lake is occupied by a large clockwise gyre

centered at mid-lake north of the Niagara River mouth. In the center of the Lake the alongshore and mid-lake currents flow eastward; northwest of Rochester there appears to be a small nearshore counterclockwise eddy driven by the Genesee River discharge. Northeast of Rochester there is a large counterclockwise gyre that is driven by the prevailing winds (transport to right of wind) and which may be confined to the southern half of the lake; the outflow current flows eastward north of this gyre. This general circulation, a clockwise gyre in the west and a counterclockwise gyre in the east, corresponds to the transport pattern presented by Simons (1971 and 1972).

Southwesterly Winds - Figure 63d

The surface current analysis shown was based on the sediment distribution pattern on ERTS-1 images obtained 19 August 1972, 6 September 1972, and 19 September 1973 during prevailing southwesterly wind regimes. As discussed above for southerly winds and by Simons (1972), there exists a counterclockwise gyre in the southeast part of the lake. The central area is occupied by general eastward-flowing currents from the Canadian shore to the U.S. shore. Under southerly wind conditions, a small eddy was observed alongshore northwest of Rochester; under southwesterly winds, these currents at that point flow clearly offshore, inducing a small area of upwelling alongshore. There may also be a small counterclockwise eddy along the Ontario shore at Point Petre, in an area where the eastward-flowing current approaches the St. Lawrence River exit. No imagery was available for the western portion of the lake under this wind condition. The general circulation cell in the eastern basin as shown in Figure 63d is unsupported by the findings of Simons and Jordon (1972). They described a clockwise gyre under generally westerly wind regimes as a result of their

numerical model.

Westerly Winds - Figure 63e

The unusually complete analysis shown here was based on the four ERTS-1 overpasses for 16 May 1973, 23 June 1973, 9 and 29 July 1973. As discussed above under northerly winds, there is a large counterclockwise gyre located in the west end of the lake beginning at Toronto on the north shore, the eastward extent of the gyre is indeterminate. All alongshore currents flow generally eastward, as do the currents at mid-lake. Beginning east of Toronto there is a cross-lake current that flows southeastward to join the outflow current at mid-lake. Alongshore northwest of Rochester there may be a small counterclockwise eddy identical to that found for southerly winds. Northeast of Rochester is the large semipermanent counterclockwise gyre similar to that existing for other wind regimes; in this case it appears to occupy the entire surface of the lake east of Rochester. Confined to the far northeast portion at the head of the St. Lawrence River is another, smaller, counterclockwise feature. The general circulations in the western and eastern basins shown in Figure 63e are in direct conflict with the computed surface current analyses indicated by Simons and Jordon (1972); however their computation was based on a one-day wind stress.

Northwesterly Winds - Figure 63f

Five clear ERTS-1 overpasses (20 August 1972, 12 April 1973, 29 April 1973, 2 June 1973, 11 July 1973) were used to develop the surface current diagram for northwesterly winds. There is a broadly-defined counterclockwise circulation in the western half of the lake. The Niagara River plume is split by the wind into a radial pattern and may represent the eastern limit of the gyre. Along the south shore a sharply-defined nearshore current is periodically interrupted by equally-strong offshore currents,

suggesting that perhaps there exists a series of small cells between the Niagara River and Rochester; upwelling is certainly occurring where the currents flow offshore. In the center of the lake, currents flow south-eastward from the Canadian shore to merge with the currents flowing eastward alongshore from Rochester. A counterclockwise gyre exists again in the eastern end, but it is smaller and displaced northward from its location under southerly to westerly wind regimes (Simons, 1972). An extensive analysis for northwesterly winds is presented by Simons and Jordon (1972); they described a counterclockwise eddy in the western basin and a large well-defined clockwise circulation over the entire central portion of the lake. The data used to construct Figure 63f are inconclusive over the central lake, but it is likely that the large clockwise gyre has been established, judging from the directions of the currents along the north and south shores. The counterclockwise gyre in the east basin shown in Figure 63f corresponds to the circulation described by Simons and Jordon (1972) as a strong counterclockwise gyre located in the southeast portion.

Summary

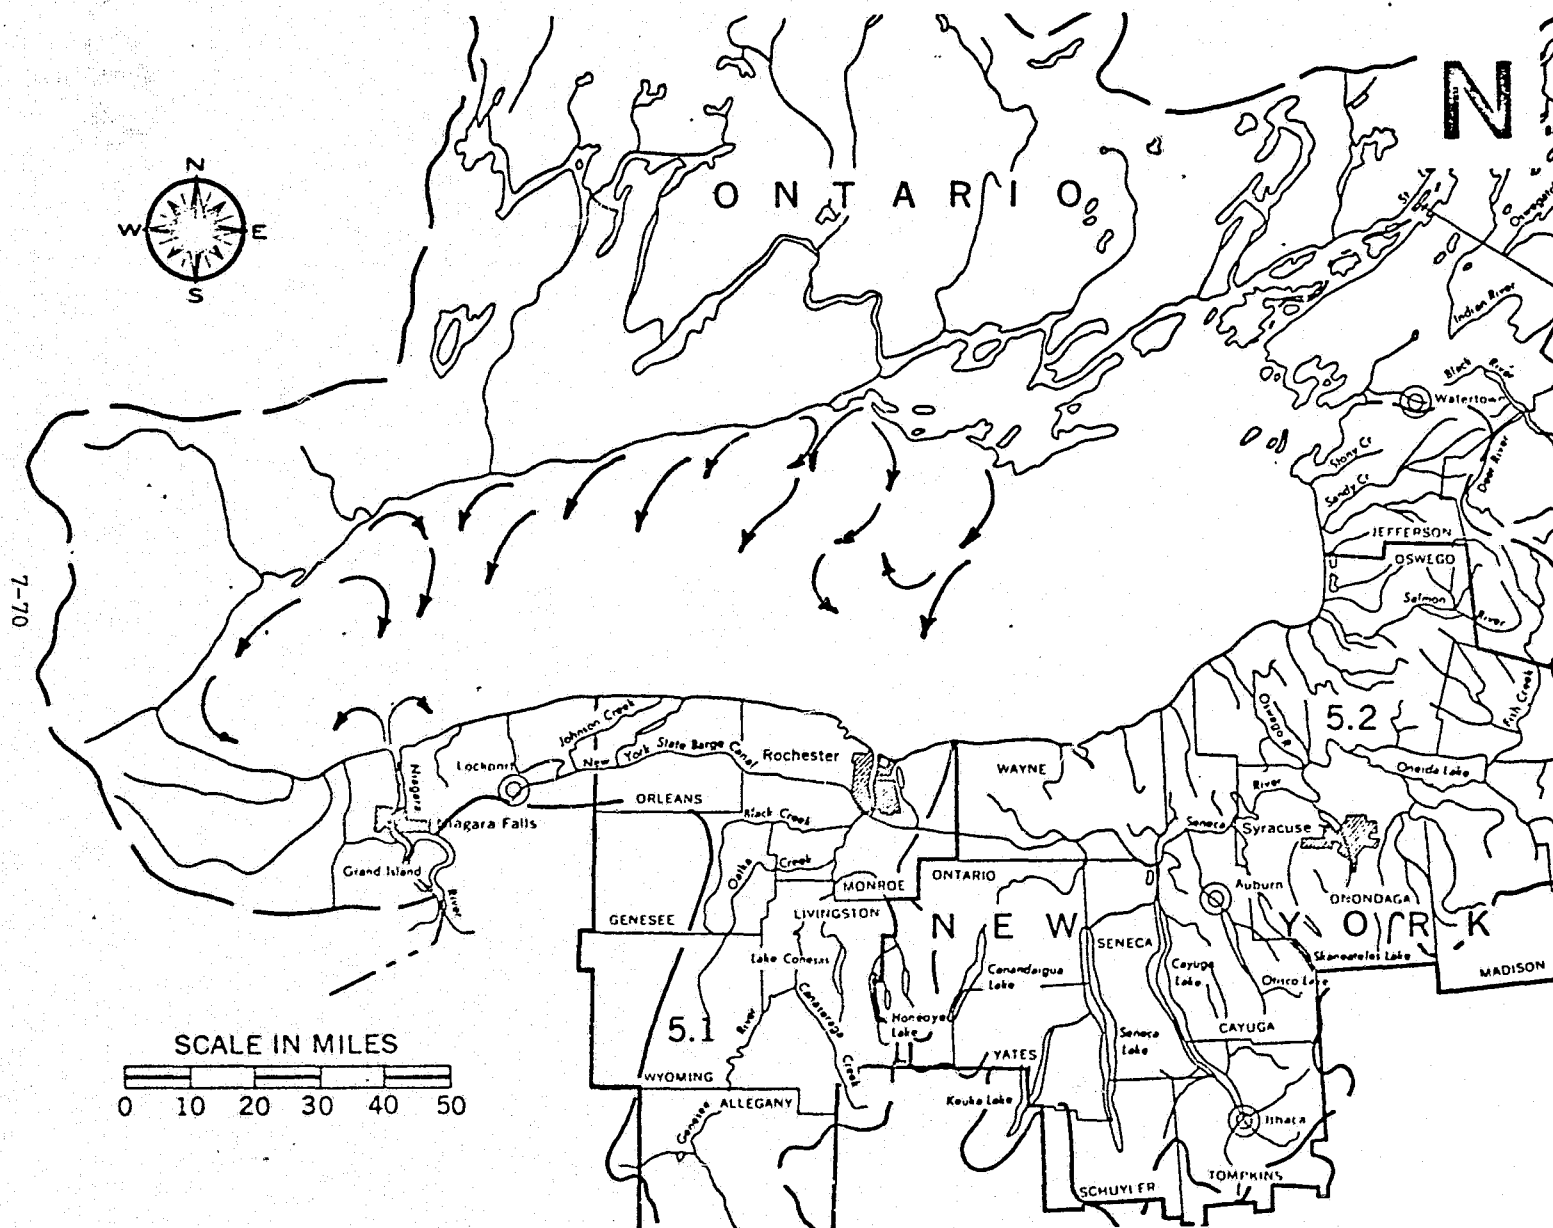

Across-lake winds from the north and south induce eddy-like circulation in surface waters of Lake Ontario. Counterclockwise alongshore flow persists in the western basin under most wind conditions. This circulation reverses direction (clockwise) under southerly (and probably southeasterly and southwesterly) wind stress. Along the southern (New York) shoreline of Lake Ontario an eastward flow is typical, as is the case in Lake Erie. As was also observed in Lake Erie, the northwesterly wind stress produces considerable offshore flow along the southern shore. Under southerly and probably southeasterly wind stress conditions the effluent of the Niagara River is carried northward out into the center of the Lake. Northeast (and

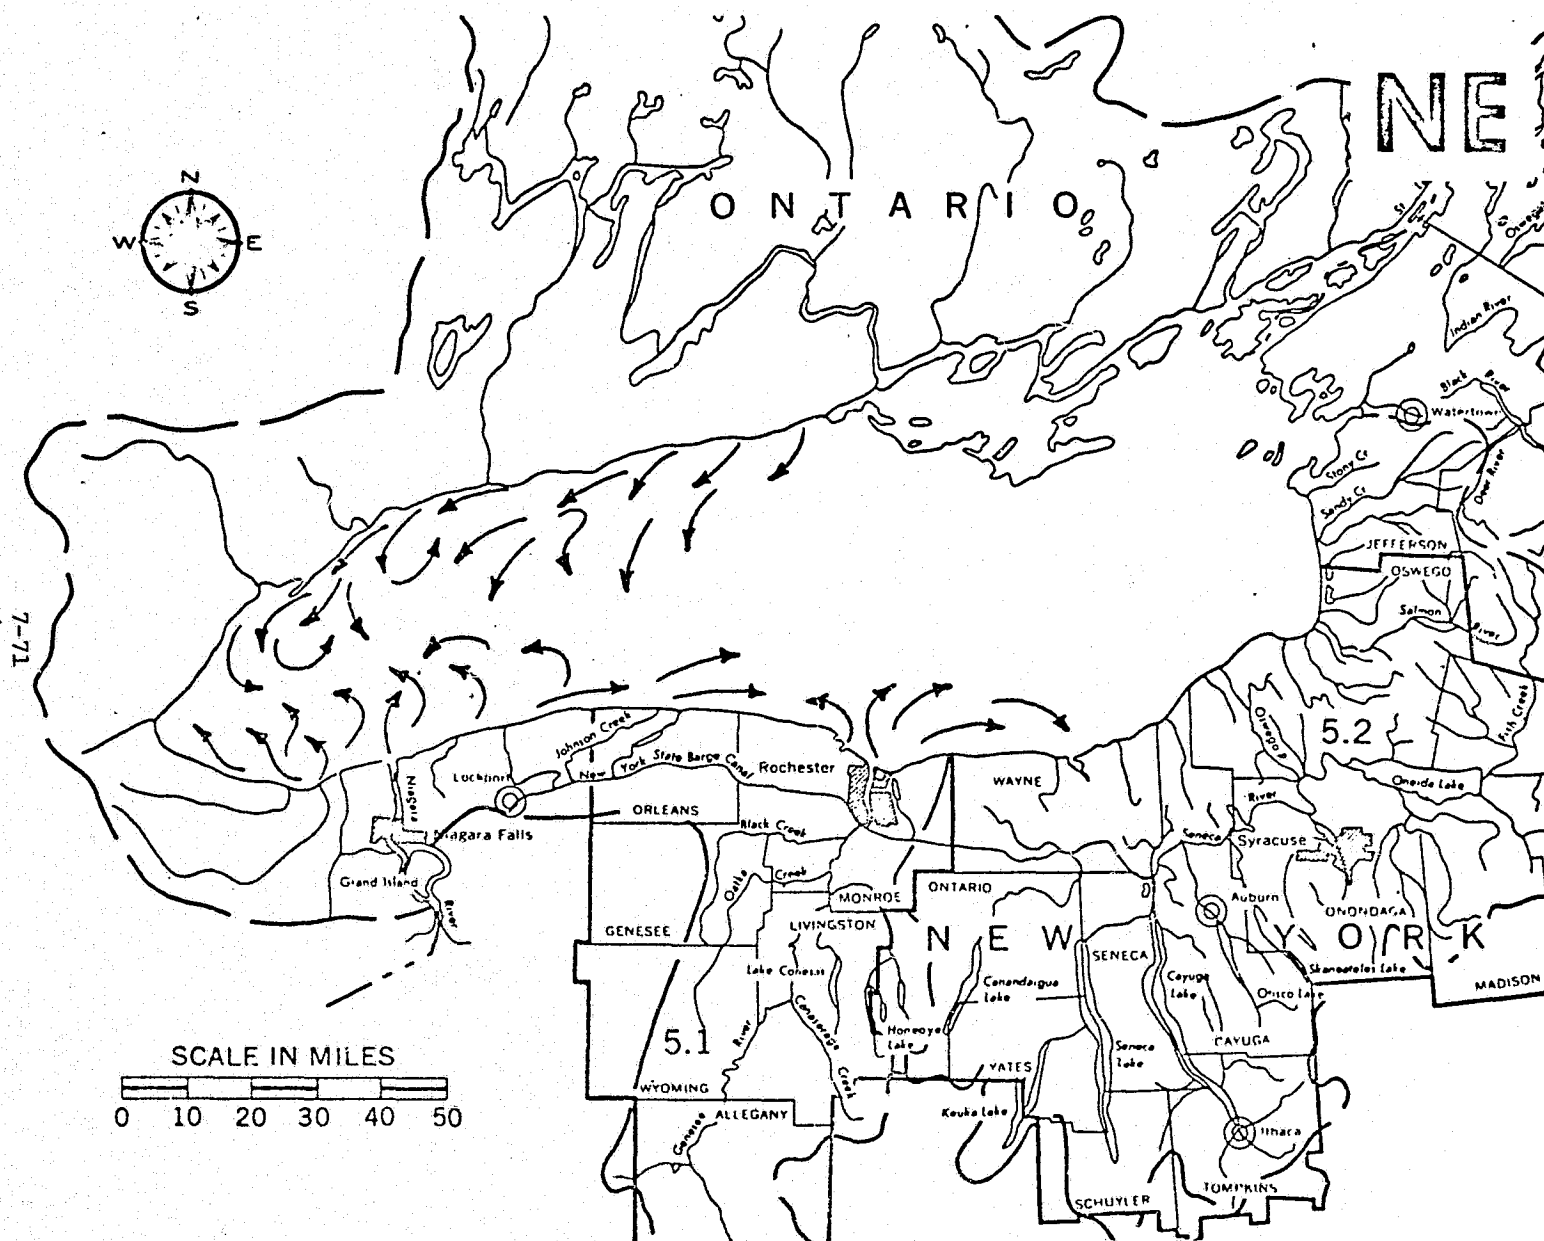

probably easterly) wind stress also favors this condition. East of Rochester eastward flow was observed exclusively.

Along the Canadian shoreline east of Toronto, eastward currents prevail. Under northwesterly stresses, however, a divergent flow begins mid-way between Toronto and Point Petre. Complete reversal to a westward flow occurs for northerly and northeasterly wind stresses (also probable under easterly winds).

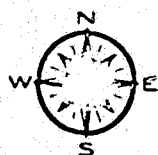

Westerly and southwesterly winds route the surface currents most straightforwardly through the lake from west to east whereas the opposite resultant winds introduce complexities to the circulation pattern.

Figure 63a-f. Surface current analyses for Lake Ontario as determined from turbidity patterns in ERTS-1 scenes. Weighted wind directions from Table A6 are indicated in upper right-hand corners.
